Recent research has fully recorded the facts of development of the rare New Zealand reptile Sphenodon, and it has more than justified the conclusion that it is the sole survivor of an originally extensive and primitive group, the Rhynchocephalia, as now understood. To confine our attention to its skeleton, as that portion of its body which can alone be compared with both the living and extinct, it may be said that positive proof has been for the first time obtained that the developing vertebral body of the terrestrial vertebrata passes through a paired cartilaginous stage, and that in its details the later development of this body is most nearly identical with that of the lower Batrachia. There has long been a consensus of opinion that the forward extension of the pterygoids to meet the vomers in the middle line, known hitherto in this animal and the crocodiles alone, is for the terrestrial Vertebrata a primitive character; and proof of this has been obtained by its presence in all the Rhynchocephalia known. The same condition has also been found to exist in the Plesiosaurs, the Ichthyosaurs, the Pterodactyles, the Dicynodontia, the Dinosaurs, and with modification in some Chelonians. It has, moreover, been found in living birds; a most welcome fact, since Archæopteryx, in the possession of a plastron, carries the avian type a stage lower than the Dinosaurs. It is pertinent here to remark that, inasmuch as in those Dinosaurs (*e.g.* Compsognathus) in which the characters of the hind limbs are most nearly avian, the pelvis, in respect to its pubis, is at the antipodes of that of all known birds, and the fore-limb is shortened in excess of that of Archæopteryx itself, the long supposed dinosaurian ancestry for birds must be held in abeyance.

Passing through the Rhynchocephalia to the Batrachia, we have to countenance progress most definite in its results. The skull, the limbs and their girdles are chiefly concerned, and this in a very remarkable way.

In the year 1881 there was made known by Prof. Froriep, of Tübingen, the discovery that the hypoglossus nerve of the embryo mammal is possessed of dorsal ganglionated roots. Again and again have I heard Huxley insist on the fact that the ventral roots of this nerve are serial with the spinal set, but never did he suspect the rest. It is, however, a most intensely interesting fact that, whereas by a Huxleian triumph the vertebral theory of the skull was overthrown, in these later Huxleian days the proof of the incorporation of a portion of the vertebral region of the trunk into the mammalian occiput should have marked the succeeding epoch in advance. The existence of twelve pairs of cranial nerves which all the Amniota possess involves them in this change; and the fact that in all Batrachia there are but ten, enables us to draw a hard-and-fast line between batrachian and amniote series.

It may be urged, as an objection, that since we have long been familiar with a fusion of vertebræ and skull in various piscine forms, the force of this distinction is weakened. But this cannot be; since, in respect to the investing sheaths and processes of development which lie at the root of the genesis of the vertebral skeleton, the fishes stand distinct from the Batrachia and Amniota, which are agreed. So forcible is this consideration that it behoves us to express it in words, and I have elsewhere proposed to discriminate between the series of terrestrial Vertebrata as *archae-* and *syn-craniate.*

Similarly there is no proof that any batrachian, living or extinct (and in this I include the Stegocephala as a whole) possesses a costal sternum. So far as their development is known, the cartilages in these animals called "sternal" are either coracoidal or *sui generis*. The costal sternum, like the syncraniate skull, is distinctive of the Amniota alone. Had the Stegocephala possessed it even in cartilage, there is reason to think it might have been preserved, as it has been in the colossal Mososaur Tylosaurus of the American Cretaceous. When to this it is added that whereas, in the presence of a costal sternum, the mechanism of inflation of the lung involves the body-wall, in its absence it mainly involves the mouth (as in all fishes and batrachians), the hard and sharp line between the Batrachia and Amniota may be expressed by the formula that the former are *archaecraniate* and *stomatophysous*, the latter *syncraniate* and *somatophysous*.

There are allied topics which might be considered did our time permit; but one certain outcome of this is that there is an end to the notion of a batrachian ancestry for the Mammalia. And when, on this basis, we sum up the characters demanded of the stock from which the Mammalia have been derived, we find them to be precisely those occurring outside the Mammalia in the Anomodont Reptiles alone. Beyond the sternum and skull, the chief characters are the possession of short and equal pentadactyle limbs, with never more than three phalanges to a digit, a complete fibula and clavicle, a doubly ossified coracoid, a heterodont dentition—a combination which, wholly or in part, we now associate with the Permian genera Procolophon, Pariasaurus, and others which might be named, the discovery of which constitutes one of the morphological triumphs of our time.

Beyond this, it may be added, concerning the Batrachia, that among living pedate forms the Anura have alone retained the pentadactyle state and the complete maxillo-jugal arch, and that the Eastern Tylototriton, in the possession of the latter, becomes the least modified urodele extant. These facts lead to the extraordinary conclusion that the living Urodela, while of general lowly organisation, are one and all aberrant; and it is not the least important sequel to this that, despite their total loss of limbs, the Apoda, in the retention of the dermal armour and other features which might be stated, are the most primitive Batrachia that exist.

The batrachian phalangeal formula 22343 was until quite recently a difficulty in the determination of the precise zoological position of the class; but it has now been overcome, by the discovery of a Keraterpeton in the Irish Carboniferous having three phalanges on the second digit of both fore- and hind-limbs, and by that in the Permian of Saxony of a most remarkable creature, Sclerocephalus, which, if rightly referred to the Stegocephala, had a head encased, as its name implies, in an armature like that of a fish, and the phalangeal formula of a reptile, 23454.

Passing from the Batrachia to the Fishes, we have still to admit a gap, since an interminable discussion on fingers and fins has not narrowed it in the least. In compensation for this, however, we have to record within the fish series itself progress greater, perhaps, than with the higher groups. Certainly is this the case if, as to bulk, the literature in systematics and palæontology be alone taken into account.

Of the Dipnoi our knowledge is fast becoming complete. We know that Lepidosiren forms a burrow; and, in consideration of a former monstrous proposal to regard this animal, with its fifty-six pairs of ribs, and Protopterus, with its thirty to thirty-five, as varieties of a species, it is the more interesting to find that the Congo has lately yielded a Protopterus (*P. Dolloi*) with the lepidosiren rib formula, viz., fifty-four pairs.

As a foremost result of American palæontological research we have to record the occurrence, in the Devonian of Ohio, of a series of colossal fishes known as the Arthrodira, the supposed dipnoan affinities of which are still a matter of doubt.

We have evidence that the osseous skeleton in a plate-like form first appeared as a protection for the eye of a primitive shark. And coming to recent forms having special bearings on the teachings of the rocks, we have to acknowledge the capture in the Japanese seas of a couple of ancient sharks, of which one (Cladoselachus), since observed to have a distribution extending to the far North, is a survivor from Devonian times; the other (Mitsukurina) a genus whose grotesqueness leaves no doubt of its identity with the Cretaceous lamnoid Scapanorhynchus. In the elucidation of the Sturiones and the determination of their affinities with the ancient Palæoniscidæ a master stroke has been achieved. In the Old Red genus Palæospondylus we have become familiar with an unmistakable marsipobranch, possessing, as do certain living fishes, a notochord, annulated, but not vertebrated in the strict sense of the term. The climax in Ichthyopalæontology, however, has been reached in the discovery of Silurian forms, which, there is every reason to believe, explain in an unexpected way the hitherto anomalous Pteras- and Cephalaspidians, by involving them in a community of ancestry with the primitive Elasmobranchs. The genera Thelodus, Drepanaspis, Ateleaspis and Lanarkia chief among these annectant and ancestral forms, are among the most remarkable vertebrate fossils known.

Passing to the Recent Fishes alone, the discovery which must take precedence is that of the mode of origin of the skeletogenous tissue of their vertebral column. The fishes, unlike all the higher Vertebrata, have, when young, a notochord invested in

a double sheath, there being an inner chordal sheath, an outer cuticular, which latter is alone present in all the higher groups. The skeletogenous cells, by whose activity the cartilaginous vertebral skeleton is formed, arise outside these sheaths; but whereas, when proliferating, they in one series remain outside, they in the other, by the rupture of the cuticular sheath, invade the chordal. This distinction enables us to discriminate between a *Chordal series*, which embraces the Chimæroids, Elasmobranchs and Dipnoi, and a *Perichordal*, consisting of the Teleosts, Ganoids and Cyclostomes.

In consideration of the enormity of the structural gap between the cyclostomes and the higher Vertebrata this is an extraordinary result. For be it remembered that, in addition to their well-known characters, the lampreys and hags (1) in the total absence of paired fins; (2) in the presence of branchiæ, ordinarily seven in number, fourteen in *Bdellostoma polytrema*, numerically variable in individuals of certain species between six and fourteen, and doubtfully asserted in the young of one to be originally thirty-five; and (3) in the carrying up of their oral hypopophysis by the nasal organ, whereby it perforates the cranium from above, as contrasted with all the higher Vertebrata, in which, carried in with the mouth-sac, it perforates it from beneath, exhibit morphological characters of an extraordinary kind. And if we are to express these characters in terms, we may distinguish the Cyclostomes as *apterygial* and *epicraniate*, the higher Vertebrata as *hypocraniate*.[1] But this notwithstanding, the aforementioned subdivision of the Pisces into two series, which would associate the teleosts and ganoids with the cyclostomes, as distinct from the rest, receives support from recent study of the head-kidney by a Japanese, who seeks to show that the organ so called in the Elasmobranchs is of a late-formed type peculiar to itself; and it is also in agreement with one set of conclusions previously deduced from the study of the reproductive organs.

To deal further with the fishes is impossible in this Address, except to remark that recent discovery in the Gambia that the young of the Teleostean genera Heterotis and Gymnarchus bear filamentous external gills, renders significant beyond expectation the alleged presence of these among the loaches, and shows that adaptive organs of this type are valueless as criteria of affinity.

In palæontology, as in recent anatomy, our records of detail have increased beyond precedent, often but to show how deficient in knowledge we are, how contradictory are our theories and facts.

In dismissing the fishes, I wish to comment upon our accepted terms of orientation. To speak of the median fins as dorsal, caudal and anal, of the pelvic as ventral, and of the pectoral in its varying degrees of forward translocation as abdominal or thoracic, though a convention of the past, is to-day inaccurate and absurd. I question if the time has not come at which the terms thoracic (pulmocardiac) and abdominal are intolerable, as expressing either the subdivisions of the body-cavity or anything else, outside the Mammalia, which alone possess a diaphragm. Even in the birds, to grant the utmost, the subdivision of the cœlom, if accurately described, must be into pulmonary, hyper-pulmonary and cardio-abdominal chambers; while with the reptiles the modes of subdivision are so complex that a special terminology is necessary for each of the several types extant.

In the fishes, where the pericardium is alone shut off, the retention of the mammalian terms but hampers progress. This was indeed felt by Duméril, when in 1865 he attempted a revisionary scheme. Since, however, one less fantastic than his seems desirable, I would propose that for the future the "anal" fin be termed *ventral*, the "ventral" *pelvic*; and that for the several positions of the pelvic, that immediately in front of the vent, primitive and embryonic (which is the position for the Elasmobranchs, Sturiones, Lower Siluroids and all the higher Vertebrata), be termed *proctal*, the so-called "abdominal" *pro-proctal*, the so-called "thoracic" *jugular* (in that it denotes association with the area of the "collar-bone"), and the so-called "jugular" *mental*. The necessity for this becomes the more desirable, now that it is known that a group of Cretaceous fishes (the Ctenothrissidæ), hitherto regarded as Berycoids, are in reality of clupeoid affinity, despite the fact that at this early geologic period they had translocated their pelvic fin into the jugular ("thoracic") position.

The sum of our knowledge acquired during the last twenty-eight years proves to us that, among the bony fishes, the structural combination which would give us a premaxillo-maxillary gape dentigerous throughout, a proctal pelvic fin, a heart with conal valves, would be the lowest and most primitive. Inasmuch as this character of the heart, so far as at present known, exists only among the Clupesoces (pikes and herrings and their immediate allies), these must be regarded as lowly forms; wherefore it follows that the possession of but a single dorsal fin is not, as might appear, a necessary index of a highly modified state.

Before I dismiss the vertebrates, a word or two upon a recent result of morphological inquiry which concerns them as a whole. I refer to the development of the skull. Up to 1878 it was everywhere thought and taught that the cartilaginous skull was a compound of paired elements, known as the trabeculæ cranii and parachordals, and that the former contributed the cranial wall. Huxley in 1874, from the study of the cranial nerves of fishes, had reiterated the suggestion he made in 1864, when dealing with the skull alone, that the trabeculæ might be a pair of præ-oral visceral arches, serial with those which support the mouth and carry the gills. The next step lay with the Sturgeon, in which in 1878 it was found that the cranial wall is originally distinct. And later, when the facts were more fully studied in sharks, batrachians, reptiles and birds, it became evident that the trabeculæ, though ultimately associated with the cranial wall, take no share in its formation, and that when first they appear they are disposed at right angles to the parachordals and the axis, serially with the visceral arches behind. Huxley was right; and although this consideration by no means exhausts the category of independent cartilages now known to contribute to the formation of the skull, it proves that the cartilaginous cranium, like the bony one, which in the higher vertebrate forms replaces it, is in its essence compound.

I now pass to the Invertebrata. Of the Oligochæta and Leeches I have spoken, and we may next consider the Arthropods. Of the Insecta, our knowledge has gained precision, by the conclusion that the primitive number of their Malpighian tubes is six, and by the study of development of these in the American cockroach Doryphora, which has rendered it probable they may be modified nephridia, carried in as are those of some oligochætes with the proctodeal invagination. An apparent cervical placenta has been discovered in the orthopteran Hemimerus, which would seem to suggest homology with the so-called "trophic vesicle" of the Peripatoids, as exemplified by *P. Novae-Britannica.* In this same orthopteran there have been recognised, in secondary proximity to the "lingua," reduced maxillulæ, which, fully developed and interposed between the mandible and first maxilla, in Japyx, Machilis, Forficula and the Ephemera larva, give us a fifth constituent for the insectan head. And when it is found that all the abdominal segments of the common cockroach, when young, are said to bear appendages, of which the cerci are the hindermost, we have a series of facts which revolutionise our ideas. Little less striking is the discovery that in the caterpillar of the bombycine genera Lagoa and Chrysopyga seven pairs of pro-legs occur.

The fuller study of the apertures of the tracheate body has resulted in the discovery that the Chilopoda are more nearly related to the Hexapoda than to the Diplopods; wherefore it is proposed to reclassify the Tracheata, in accordance with the position of the genital orifice, into Pro- and Opistho-gonata. In a word, the "Myriapoda," if a natural group, are diphyletic.

Our knowledge of the Peripatoids (*Arthropoda malacopoda*) has increased in all that concerns distribution and structure. They are now known, for example, from Africa, the West Indies, Australia and New Zealand, and for examples from the two latter localities and Tasmania the generic name Ooperipatus has but lately been proposed, to include three species, characterised by the possession of an ovipositor, of which two have been observed to lay eggs.

Work upon the Crustacea in our own land, notorious for the tendencies of some of its devotees in their stickling for priority, has within the last twelve years advanced beyond all expectation. Much of our literature has been systematised, and an enormous increase in our knowledge of new forms has to be admitted, thanks to memoirs such as those of the "Investigator,"

[1] It is an interesting circumstance, if their "ciliated sac" is rightly homologised, that Amphioxus and the Tunicata present a corresponding dissimilarity, allowance being made for the fact that in Botryllus, Goodsiria and Polycarpa the sac overlies the ganglion. It is pertinent here to recall the ammocœte-like condition of the "endostyle" in *Oikopleura flabellum.*

"Naples Zoological Station," and others which might be named; while in the discovery and successful monographing, in the intervals of six years' labour at other groups, of a new family of minute Copepods (the Choniostomatidæ), parasitic on the Malacostraca, embracing forty-three species, difficult to find, we have an almost unique achievement. The hand which gave us this has also provided a report which embraces the description of a nauplius of exceptional type, which, by a process of reasoning by elimination, masterly in its method, has been "run to ground" as in every degree of probability the larva of Darwin's apodal barnacle *Protolepas bivincta*, of which only the original specimen is known.

There is but one other crustacean record equal in rank with this, viz., the discovery of the genus Anaspides. Originally obtained from a fresh-water pool on Mount Wellington, Tasmania, at 4000 feet, it has since been found in two other localities. It is unique among all living forms, in combining within itself characters of at least three distinct suborders of "prawns," for with a schizopod body it combines the double epipodial lamellæ of an amphipod, the head of a decapod (pedunculated eyes and antennulary statocysts) apart from characters peculiarly its own. There is reason to believe that the nearest living ally to this remarkable creature is a small eyeless species (*Bathynella natana*) obtained from a Bohemian well; and if its presumed relationships to the Palæozoic "pod-shrimps" be correct, this heterogeneous assemblage may perhaps be the representatives of a group of primitive Malacostraca, through which, by structural divergence, the establishment of the higher crustacean suborders may have come about.

It is pertinent to this to note that work upon cave-dwelling and terrestrial forms, upon "well-shrimps" and the like, has produced important results. And interesting indeed is the recent discovery of three species. living at 800–900 feet above sea-level, in Gippsland, one an amphipod, two of them isopods, which, though surface-dwellers, are all blind. While they prove to be species of genera normally eyed, they in their characters agree with well-known American forms; and the bleaching of their bodies and atrophy of their eyes proclaim them the descendants of cave-dwelling or subterranean ancestors, among whom the atrophy took place.

Huxley in 1880 rationalised our treatment of the higher Crustacea, by devising a classification by gills, expressive of the relationships of these to the limb-bases, interarticular membranes and body-wall. Hardly had his influence taken effect when, by work extending over the years 1886 to 1893, in the study of Penæus, the Phyllopods, Ostracods and other forms, evidence had been accumulating to show that the crustacean appendage, even to the mandible itself, has primarily a basal constituent (protopodite) of three segments; that the branchiæ one and all are originally appendicular in origin; and that the numerical reduction of the basal (protopoditic) segments to two, with the assumption of a non-appendicular relationship by the gills, is due to coalescence of parts, with or without suppression. The evidence for this epoch-making conclusion, which simplifies our conceptions and brings contradictory data into line, is as irresistible as it is important, and there has been nothing finer in the whole history of crustacean morphology. With it, the attempt to explain the supposed anomalous characters of the antennule by appeal to embryology goes to the wall; and, taking a deep breath, we view the Crustacea in a new light.

There remains for brief consideration one carcinological discovery second to none which bears on the significance of larval forms. It is that of the Trilobite *Triarthrus Becki*, obtained in abundance from the Lower Silurian near New York, with all its limbs preserved. In the simplicity of its segmentation and the biramous condition of its limbs it is primitive to a degree. Chief among its characters are the total absence of jaws in the strict sense of the term, and the fact that of its three anterior pairs of appendages the third is certainly and the second is apparently biramous, the first uniramous and antenniform. In this we have a combination of characters known only in the nauplius larva among all living crustacean forms; and the conclusion that the adult trilobite, like that of the Euphausiaceæ, Sergestidæ, Penæidæ, the Ostracods and Cirripedes of to-day, was derived by direct expansion of the nauplius larva can hardly be doubted. Much yet remains to be done with the study of the Triarthrus limbs; and the suggestion of a foliaceous condition by those of the pygidium, which are youngest, is a remarkable fact, the meaning of which the future must decide. We should expect the condition to be a provisional one, since while we admit the primitive nature of the phyllopods as an Order, we cannot regard the foliation of their appendages as anything but a specialisation. Be this as it may, the structural community between the nauplius larva and the trilobite is now proved; and when we add that in the yolk-bearing higher Crustacean types (*e.g.* Astacus) a perceptible halt in the development may be observed at the three-limb-bearing stage; that in Mysis the vitelline membrane is shed but to make way for a nauplius cuticle; and that the median nauplius eye has long been found sessile on the adult brain of representative members of the higher crustacean groups, up to the lobster itself, our belief in the ancestral significance of the nauplius larval form is established beyond doubt.

The thought of the nauplius suggests other larval forms. The gastrula is no longer accepted without reserve; the claims of the blastula, planula, parenchymella, not to say the plakula, have all to be borne in mind. It is of the Trochophore, however, as familiar as the nauplius, that I would rather speak, as influenced by recent research. It is supposed to be primitive for the molluscs and chætopod worms at least; and various attempts have been made to bolster it up, and to show that if we allow for adaptive change, its characters, well known, are constant within the limits of its simpler forms.

It is now more than forty years ago that the late Lacaze-Duthiers described for Dentalium a larval stage, characterised by the possession of recurrently ciliated zones, which by reduction, with union and translocation forwards, give rise to the trochal lobe. It is now known that in the American pelecypod *Yoldia limatula* a similar stage is found, in which a "test," of five rows of ciliated cells, is present; and of the young of *Dondersia banyulensis* the like is true. But whereas in the Yoldia the ciliated sac is ultimately shed, in the Myzomenian the escape of the embryo is accompanied by rupture which liberates the anterior series of ciliated zones in a manner strongly suggestive of forward concentration, leaving the posterior circlet with its cilia attached.

This "test" has also been seen in two species of Nucula, and pending fuller inquiry into the Myzomenian and a reinvestigation of Dentalium, I would suggest that this recurrently ciliated sac is representative of a larval stage antecedent to the trochophore, for which the term *protrochal* may suffice. This term has indeed been already applied to a larva of certain Polychæta, which might well represent a modification of that for which I am arguing; and quite recently it appears to have been observed near Ceylon for a species of the genus Marphysa.

The discovery of this larva in Dondersia was accompanied by that of a later-formed series of dorsal spicular plates, which for once and for all, in realising a chitonid stage, demolish the heresy of the "Solenogastres," mischievous as suggesting an affinity with the worms. Like that of the supposed cephalopod affinities of the so-called "Pteropods," it must be ignored as an error of the past.

Returning to the protrochal stage, whatever the future may reveal concerning it, by bringing together the Lamellibranchiata, Scaphopoda and Polyplacophora, it associates in one natural series all the bilaterally symmetrical Mollusca except the cephalopods. In doing this, it deals the death-blow to the supposed Rhipidoglossan affinity of the Lamellibranchiata; and in support of this conclusion I would point out that the recently discovered eyes of the mytilids are in the position of those of the embryo Chiton, and that just as Dentalium, in the formation of its mantle, passes through a lamellibranchiate stage, so are there lamellibranchs in number in which a tubular investment is found.

This protrochal larva has an important part to play. It may very possibly explain phenomena such as the compound nature of the trochal lobe of the limpet, the presence of a post-oral ciliated band in the larva of the ship-worm, and of a præ-anal one in that of various molluscan forms. In view of it, we must hesitate before we fully accept the belief in the ancestral significance of the trochophore. And it is certain that an idea, at one time entertained, that the Rotifer (Trochosphæra) which so closely resembles it as to bear its name is its persistent representative is wrong, since this is now known to be but the female of a species having a very ordinary male.

Through the Rhipidoglossa we pass to the Gastropods, which are one and all asymmetrical, for even Fissurella, Patella and Doris, when young, develop a spiral shell; while Huxley in 1877 had observed that the shell of Aplysia, in its asymmetry, betrays its spiral source.

The notion, which until recently prevailed, that among these gastropods the non-twisted or so-called euthyneurous condition of the visceral nerve-cords, as exemplified by the Opisthobranchs, is a direct derivative of that of the Chitons has been proved to be erroneous, since the nerves in Actæon and Chilina, like those of the prosobranchs, are twisted or streptoneurous. And as to the torsion of the gastropod body, recent research, in which one of my pupils has played a part, involving the discovery of paired reno-pericardial apertures in Haliotis, Patella and Trochus, has resulted in proof that the dextral torsion which leads to the monotocardiac condition does not uniformly affect all organs lying primitively to the left of the rectum, as we have been taught; since, concerning the renal organs, it is the *primitively* (pretorsional) left one which remains as the functional kidney, its ostium as the genital aperture. Nor is the primitively right kidney necessarily lost, for while its ostium remains as the renal orifice, its body, by modification and reduction, may become an appendage of the functional kidney, the so-called nephridial gland. And we now know there are cases of sinistral torsion of the visceral bump, in which the order of suppression of the organs is not reversed, the arrangement being one of adaptation of a dextral organisation to a sinistral shell.

Though thus specialised and asymmetrical as a group, the gastropods are yet plastic to an unexpected degree. Madagascar has yielded a Physa (*P. lamellata*) with a neomorphic gill, a character shared by species of Planorbis (*P. corneus* and *P. marginatus*), and an Ancylus in which the lung-sac is suppressed; while St. Thomas's Island has given us a snail (*Thyrophorella Thomensis*), the peristome of whose shell is produced into a protective lid.

In palæontology, history records the fact that in 1864 Huxley observed that the genus Belemnites appears to have borne but six free arms; a startling discovery which lay dormant till the present year. And the recent study of the fauna of the great African lakes, in bringing to light the existence of a halolimnic molluscan series in Lake Tanganyika, has opened up new possibilities concerning the palæontological resources of enormous aqueous deposits, recently discovered in the interior, and has entirely changed our geological conceptions of the nature of Equatorial Africa.

Time prevents my dealing with other groups, and it must suffice to say that with those I have not considered substantial work has been done. From what has been said, it is natural to expect that in some direction or another so vast an accumulation of facts must have extended the Darwinian teaching; and it is now quite clear that this has been the case with the two post-Darwinian principles known as "Substitution" and Isomorphism or "Convergence."

The former may be exemplified by nothing better than the case of the Rays and Skates, in which, under the usurpation of the propelling function of the tail by the expanded pectoral fins, the tail, free to modify, becomes in one species a lengthy whiplash, in another a vestigial stump, in others, by the development of powerful spines, a formidable organ of defence. In both the Rays and certain other fishes subject to the working of this law, modification goes further still, in the appearance of electric organs in remotely related genera and species, by specialisation of the muscular system of the trunk or tail, or, as in the case of Malapterurus, of "tegumental glands." In this we have a difficulty admitted by Darwin himself, which now becomes clear and intelligible, since there is nothing new. There has simply come about the conversion, in one case of the energy of muscular contraction, in the other of glandular secretion, into that of electrical discharge, with accompanying structural change. The blind locust (*Pachyramina fuscifer*) of the New Zealand Limestone caves presents an allied case, since here, under the reduction of the eye, the antennæ, elongated to a remarkable degree, have become the more efficiently tactile; and it is an interesting question whether this principle may not explain the attenuation of the limbs in the recently discovered American Proteoid (*Typhlomolga Rathburni*) of the Texan subterranean waters.

And as to isomorphism, by which we mean the assumption of a similar structural state by members of diverse or independent groups, I would recall the case of the Eocene Creodont Patriofelis and the Seals, and that of the Myriapods to which I have already alluded, and would cite that of the Dinosaurs and Birds, heterodox though it may appear, for reasons I have given.

As our knowledge increases, there is every reason to believe that, in the non-appreciation of these principles in the past, not a few of our classifications are wrong. We have even had our bogies, as, for example, the so-called Physemaria, which deceived the very elect; and before I close I wish to deal briefly with a question of serious doubt, which these considerations suggest.

It is that of the position in the zoological series of the Limuloids, popularly termed the King Crabs. These creatures, best known from the opposite shores of the Northern Pacific, but found in the oriental seas as well as far south as Torres Strait, have been since 1829 the subject of a difference of opinion as to their zoological position and affinities. Within the last twenty years there have been three determined advances upon them, and of these the third and most recent may be first discussed. It has for its object the attempt to prove that they are intimately associated with the cephalaspidian and other shield-bearing fishes of the Devonian and Silurian epochs, and that through them they are ancestral to the Vertebrata. The latest phase of this idea is based on the supposed existence in a Cephalaspis of a series of twenty-five to thirty lateral appendages of arthropod type. When, however, it is found that the would-be limbs are but the edges of body-scutes misinterpreted, suspicion is aroused; and when, working back from this, an earlier attempt reveals the fact that the author, compelled to find trabeculæ, in order to force a presupposed comparison between the architecture of the Cephalaspidian head-shield and the Limulus' prosomal hood, resorts to a comparison between the structure of the former in general and that of the cornu of the latter, with details which on the piscine side are not to date, the argument must be condemned. It violates the first principles of comparative morphology, and is revolting to common sense; and as to the fishes concerned, we know that they have nothing whatever to do with the Limuloids, for we have already seen that, with their allies the Pteraspidiæ, they are a lateral branch of the ancestral piscine stem.

The second advance upon the king crabs has very much in common with the first. It has engrossed the attention of an eminent physiologist for the last six or seven years, and by him it was in detail set before Section I at our meeting of 1896. Suffice it to say that it specially aims at establishing a structural community between the king crabs and certain vertebrates, favourable to the conviction that the Vertebrata have had an arthropod ancestry. When we critically survey the appalling accumulation of words begotten of this task, it is sufficient to consider its opening and closing phases. At the outset, under the conclusion that the vertebrate nervous axis is the metamorphosed alimentary canal of the arthropod ancestor, the necessity for finding a digestive gland is mainly met by homologising the so-called liver of the arthropod with the cellular arachnoid of the larval lamprey, in violation of the first principles of comparative histology! At the close we find ingenious attempts to homologise nerve tracts and commissures related to the organs of sense, such as are invariably present wherever such organs occur. Sufficient this to show that the comparison, in respect to its leading features, is in the opening case strained to an unnatural degree, in the closing case no comparison at all. Finding, as we do, that the rest of the work is on a par with this, we are compelled to reject the main conclusion as unnatural and unsound; and when we seek the explanation of this remarkable course of action, we are forced to believe that it lies in the failure to understand the nature of the morphological method. For the proper pursuit of comparative morphology, it is not sufficient that any two organisms chosen here and there should be compared, with total disregard of even elementary principles. Comparison should be first close and with nearly related forms, passing later into larger groups, with the progressive elimination of those characters which are found to be least constant. And necessary is it, above all things, that in instituting comparison it should be first ascertained what it is that constitutes a crustacean, a marsipobranch a cyclostome, and so on for the rest. We have tried to accept this theory, fascinated both by the arguments employed and by the idea itself, which for ingenuity it would be difficult to beat, but we cannot; and we dismiss it as misleading, as a fallacy, begotten of a misconception of the nature of the morphological method of research. It is of the order of events which led Owen to compare a cephalopod and a vertebrate, led Lacaze-Duthiers to regard the Tunicata and Lamellibranchs as allied; and with these and other heresies it must be denounced.

Passing to the third advance, extending over the last twenty years, it may be said to consist in the revival of a theory of 1829, which boldly asserts that Limulus is an Arachnid. In the development of the defence there have been two weak points but lately strengthened, viz., the insufficient consideration of the palæontological side of the question and of the presence of tracheæ among the Arachnida. Under the former there was, until recently, assumed the absence of the first pair of appendages in the Eurypterida; but it may be said that they have since been observed in *Eurypterus Fischeri* of the Russian Silurian, and *E. scoticus* from the Pentland Hills, in both of which they consist of small chelate appendages flexed and limuloid in detail, somewhat reduced perhaps, and enclosed by the bases of the succeeding limbs, which become apposed as the anterior end is reached. Since by this discovery the Limuloids, Eurypterids and Scorpionids are brought into a numerical harmony of limb-bearing parts, we may at once proceed to other points at issue. So far as the broader structural plan of Limulus and the Scorpion are concerned, all will agree to a general community, except for the organs of respiration; but concerning the cœlom, the mobile spermatozoa and the more detailed features under which Limulus is held to differ from the Crustacea and to resemble the Arachnida, I would remark that while motile spermatozoa are characteristic of the Cirripedes, the rest of the argument is weakened, by the probability that the "arachnidan" characters which remain may well have been possessed by the crustacean ancestors, and that Limulus, though specialised, being still an ancient form, might have retained them. The difficulty does not seem to me to lie in this, or with the excretory organs, if we are justified in accepting the aforementioned argument that the so-called Malpighian tubes may be inturned nephridia, ectodermal in origin, and in knowledge of the existence of endodermal excretory diverticula in the Amphipods. These facts would seem to suggest that as our experience widens, differences of this kind will disappear.

As to the tracheal system, now adequately recognised by the upholders of the arachnid theory, the presumed origin of tracheæ from lung-books, the probability that the ram's-horn organ of the Chernetidæ may be tracheal, the presence of tracheæ in a simple form in the Acari, and, by way of an anomaly, in a highly organised form on the tibiæ of the walking legs of the harvestmen (Phalangidæ), are all features to be borne in mind. While I am prepared to admit that this wide structural range and varied distribution of the tracheæ lessens their importance as a criterion of affinity, I cannot accept as conclusive the evidence for the assumed homology between lung-books and gills. And here it may be remarked that a series of paired abdominal vesicles, recently found in the remarkable arachnid Kœnenia, invaginate as a rule but in one example everted, seized upon in defence of this homology, have not been so regarded by those most competent to judge.

There remains the entosternite, an organ upon which much emphasis has been placed. Not only does a similar organ exist, apart from an endophragmal system, in Apus, Cyclops, some Ostracods and Decapods, but, regarding the question of its histology, it may be pointed out that, from all that is at present known, the structural differences between these several entosternites do not exceed those between the cartilages of the Sepia body. And when it is found that the figures and descriptions of the entosternite of Mygale ("Mygale sp.," "Mygalomorphous Spider," *auct.*) have been thrice presented upside down! the reliability of this portion of the argument is lessened, to say the least.

Recent observation has sought to clench the homology of the four posterior pairs of limbs of the King Crab and Scorpion, by appeal to a furrow on the fourth segment in the former, believed to denote an original division into two; but I hesitate to accept this until myological proof has been sought.

Returning, amidst so much that is problematic, to the sure ground of palæontology, I wish to point out that when all is considered in favour of the arachnid theory there still remains another way of interpreting the facts.

In both Limulus and the Scorpion the first six of the eighteen segments are well known to be fused into a prosoma bearing the limbs, but while in the Scorpion the remaining twelve are free, in Limulus they are united into a compact opisthosomal mass. In dealing with the living arthropods, there is no character determinative of position in the scale of this or that series more trustworthy than the antero-posterior fusion of segments. It has been called the process of "cephalisation," and the degree of its backward extension furnishes the most trustworthy standard of highness or lowness in a given assemblage of forms. In passing from the lower to the higher Crustacea, we find this fusion increasing as we ascend: and it therefore becomes necessary to compare the Scorpion with the other Arachnida, Limulus with the Eurypterida, in order the better to determine the position of each in its respective series, by the application of this rule.

As to the number of segments present, variation is a matter of small concern, in consideration of the mode of origin of segmentation and the wide numerical range—from seven in the Ostracods to more than sixty in Apus—the segments of the crustacean class present.

On the arachnidan side, in the Solifugæ but the third and fourth segments are fused; the remaining four of the prosomal series with the ten which remain are free. In Kœnenia four of the prosomal segments alone unite; the fifth and sixth with the rest are free. And when we pass to the Limuloids and the descending series of their allies, we find it distinctive of the Eurypterida that all the opisthosomal segments are free. If we can trust these comparisons, we must conclude that the Eurypterida of the past, in respect to their segmentation, simplify the Limuloid type, on lines similar to that on which the Solifugæ and Kœnenia simplify the Higher Arachnid and Scorpionid type, and that therefore, if the degree of antero-posterior fusion of segments has the significance attached to it, Limulus and Scorpio must each stand at the summit of its respective series. If this be admitted, it has next to be asked if, in comparing them, we may not be comparing culminating types, which might well be isomorphic.

The scorpions are known fossil by two genera, Palæophonus and Proscorpius, from the Silurian of Gotland and Lanarkshire, the Pentland Hills and New York State; while recent research, in the discovery of the genus Strabops, has traced the Eurypterida back to the Cambrian, leaving the scorpions far behind. One striking feature of the limbs of the Palæozoic Eurypterids is their constantly recurring shortness and uniformly segmented character, long known in Slimonia, and less conspicuously in Pterygotus itself, retained with development of spines in three of five known appendages of the recently described eurypterid giant Stylonurus. The minimum length yet observed for these appendages is that of the Silurian species *Eurypterus Fischeri*, discovered by Holm in Russia in 1898. This creature is one of the few eurypterids in which all the appendages are preserved, and it is the more strange therefore that the advocates of the arachnid theory should ignore it in their most recent account. Allowing for the specialisation of its sixth prosomal appendage for swimming, the fifth is but little elongated, the second, third and fourth are each in total length less, by far, than the transverse diameter of the prosoma, and uniformly segmented, giving the appearance of short antennæ. They seem to be seven-jointed, and are just such appendages as exist in the simpler crustacean and tracheate forms; and in the fact that their structural simplicity is correlated with the independence of the whole series of opisthosomal segments they lend support to the argument for isomorphism.

With this conclusion, we turn once more to the Scorpions, if perchance something akin to it may not be in them forthcoming. The Silurian genus Palæophonus, especially as represented by the Gotland specimen, reveals the one character desired. Its body does not appear to be in any marked degree simpler than that of the living forms; but on turning to its limbs, we find the four posterior pairs, in length much shorter than those of any living species, all but uniformly segmented. In this they approximate towards the condition of the limbs of the Eurypterida just dismissed, and their condition is such that had they been found fossil in the isolated state they would have been described as the limbs of a Myriapod, and not of a scorpion at all. Indeed, their very details are what is required, since in the possession of a single terminal claw they differ from the limbs of the recent scorpions as do those of the Chilopoda from the hexapods.

With this the scorpionid type is carried back, with a structural simplification indicative of a parallelism with the other arthropod groups; and while the facts do not prove the total independence of the scorpionid and limuloid series, they bring the latter into closer harmony with the Eurypterida of the past. They prove that the Silurian Scorpions simplify the existing Scorpionid type, on precisely the lines on which the Eurypterida simplify the Limuloid; and they do so in a manner which suggests that a distinction between the *Crustacea vera* and the *Crustacea gigantostraca* (to include the Eurypterida and

Xiphosura) is the nearest expression of the truth. It becomes thereby the more regrettable that in a recent revision of the taxonomy of the Limuloids the generic name Carcinoscorpius should have found a place.

I foresee the objection that the antenniform condition of the shorter limbs may be secondary and due to change. There is no proof of this. Against it, it may be said that the number of the segments is normal, and that where nature effects such a change, elongation is with the multi-articulate state the only process known; as, for example, with the second leg of the Phrynidæ, the so called second pareiopod of the Polycarpidea and the last abdominal appendage of Apseudes.

That advances such as we have now considered should lead to new departures is a necessity of the case; and it but remains for me to remind you that within the last decade statistical and experimental methods have very properly come more prominently into vogue, in the desire to solve the problems of variation and heredity. Of the statistical method, by no means new, I have but time to recall to you the Presidential Address of 1898 by my friend and predecessor in this chair, himself a pioneer; and of the experimental method I can but cite an example, and that a most satisfactory one, justifying our confidence and support. It concerns the late Prof. Milne-Edwards, who in 1864 described, from the Paris Museum, the head of a rock lobster (*Palinurus penicillatus*), having on the left side an antenniform eye stalk. With the perspicuity distinctive of his race, he argued in favour of the "fundamental similarity of parts susceptible to revert to their opposite states." The matter remained at this till, on the removal of the ophthalmite of certain Crustacea, it was found that in regeneration it assumes a uniramous multiarticulate form; and it is an interesting circumstance that in the common crayfish the biramous condition normal to the antennule may occur. An example this of a fact which no other method could explain.

When all is said and done, however, it is to the morphological method that I would appeal as most trustworthy and sound. And when we find (1) that in certain compound Tunicates the atrial wall, in the egg development delimited by a pair of ectoblastic invaginations, in the bud development may be formed from the parental endodermic branchial sac; (2) that regenerated organs are by no means derivative of the blastemata whence they originally arose; (3) that in the development of a familiar star-fish the inner cells of the earliest segmentation stages, by intercalation among the outer, contribute half the fully-formed blastula; (4) that there are Diptera in existence in which, while it is well-nigh impossible to discriminate between the adult forms, there is reason to believe the pupa cases are markedly and constantly distinct; it becomes only too evident that the later embryonic and adult states are those most trustworthy for all purposes of comparison, and that it is by these that our animals can best be known and judged. Caution is, however, necessary with senility and age, since certain skulls have been found to assume at this period characters and proportions strikingly abnormal, and by virtue of the most important discovery, which we owe to the Japanese, that in certain Holothurians the calcareous skeletal deposits may so change with age as to render specific diagnoses based on their presumed immutability invalid. Advance, real and progressive, is in no department of zoological inquiry better marked than comparative morphology, and it is for the preeminence of this that I would plead. Educationally, it affords a mental discipline second to none.

We live by ideas, we advance by a knowledge of facts, content to discover the meaning of phenomena, since the nature of things will be for ever beyond our grasp.

And now my task is done, except that I feel that we must not leave this place without a word of sympathy and respect for the memory of one of its sons, an earnest devotee to our cause. William Thompson, born in Belfast, 1806, became in due time known as "the father of Irish natural history." By his writings on the Irish fauna, and his numerous additions to its lists, he secured for himself a lasting fame. In his desire to benefit others, he early associated himself with the work of the Natural History Society, which still flourishes in this city. He was President of this Section in 1843, and died in London in 1852, while in the service of our Association, in his forty-seventh year, beloved by all who knew him. His memory still survives; and if, as a result of this meeting, we can inspire in the members of the Natural History and Philosophic Society of this city, as it is now termed, and of its Naturalists' Field Club an enthusiasm equal to his, we shall not have assembled in vain.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. JOHN PERRY, M.E., D.SC., LL.D., F.R.S., PRESIDENT OF THE SECTION.

THIS Section has had sixty-six Presidents, all different types of engineer. As each has had perfect freedom in choosing the subject for his Address, and each has known of the rule[1] that Presidential Addresses are not subject to debate afterwards, and as, being an engineer, he has always been a man of originality, of course he has always chosen a subject outside his own work. An engineer knows that the great inventions, the great suggestions of change in any profession, come from outsiders. Lawyers seem like fish out of water when trying to act as law-makers. The radical change that some of us hope to see before we die in the construction of locomotives will certainly not come from a locomotive superintendent who cannot imagine a locomotive which is not somehow a lineal descendant of the Rocket.

Hence it is that in almost every case the President of this Section has devoted a small or large part of his Address to the subject of the education of engineers. I grant that every President has devoted his life to the education of one engineer—himself—and it is characteristic of engineers that their professional education proceeds throughout the whole of their lives. Perhaps of no other man can this be said so completely. To utilise the forces of Nature, to combat Nature, to comprehend Nature as a child comprehends its mother, this is the pleasure and the pain of the engineer.[2] A mere scientific man analyses Nature; takes a phenomenon, dissects it into its simpler elements, and investigates these elements separately in his laboratory. The engineer cannot do this. He must take Nature as she is, in all her exasperating complexity. He must understand one of Nature's problems as a whole. He must have all the knowledge of the scientific man, and ever so much more. He uses the methods of the scientific man, and adds to them methods of his own. The name given to these scientific methods of his own or their results is sometimes "common-sense," sometimes "character," or "individuality," or "faculty," or "business ability," or "instinct." They come to him through a very wide experience of engineering processes, of acquaintance with things and men. No school or college can do more than prepare a young man for this higher engineering education which lasts through life. Without it a man follows only rule of thumb, like a sheep following the bell-wether, or else he lets his inventiveness or love of theory act the tyrant.

When a man has become a great engineer and he is asked how it happened, what his education has been, how young engineers ought to be trained, as a rule it is a question that he is least able to answer, and yet it is a question that he is most ready to answer. He sees that he benefited greatly by overcoming certain difficulties in his life; and forgetting that every boy will have difficulties enough of his own, forgetting that although a few difficulties may be good for discipline many difficulties may be overwhelming, forgetting also that he himself is a very exceptional man, he insists upon it that those difficulties which were personal to himself ought to be thrown in the path of every boy. It often happens that he is a man who is accustomed to think that early education can only be given through ancient classics. He forgets the dulness, the weariness of his schooldays. Whatever pleasure he had in youth—pleasure mainly due to the fact that the average Anglo-Saxon boy invents infinite ways of escaping school drudgery—he somehow connects with the fact that he had to learn classics. Being an exceptional boy, he was not altogether stupefied and did not altogether lose his natural inclination to know something of his own language; and he is in the habit of thinking that he learnt English through Latin, and that ancient classics are the best mediums through which an English boy can study anything.[3]

[1] The Committees of Sections G and L have arranged a discussion on "The Education of Engineers," this Address being regarded as opening the discussion. Thus the rule is not in force this year.

[2] Of all the unskilled labour of the present day, surely that of the modern poet is the most grotesque. How much more powerful and powerless man seems to us now; how much more wonderful is the universe than it was to the ancients! Yet our too learned poets prefer to copy and recopy the sentiments of the ancients rather than try to see the romance which fills the lives of engineers and scientific men with joy.

[3] The very people who talk so much of learning English through Latin neglect in the most curious ways those Platt-Deutsch languages, Dutch and Scandinavian, a knowledge of which is ten times more valuable in the study of what is becoming the speech of the world. And how they do scorn Lowland Scotch!

The cleverest men of our time have been brought up on the classics, and so the engineer who cannot even quote correctly a tag from the Latin grammar, who never knew anything of classical literature, insists upon it that a classical education is essential for all men. He forgets the weary hours he spent getting off Euclid and the relief it was to escape from the class-room not quite stupefied, and he advocates the study of pure mathemathics and abstract dynamics as absolutely necessary for the training of the mind of every young engineer. I have known the ordinary abominable system of mathematical study to be advocated by engineers who, because they had passed through it themselves, had really got to loathe all kinds of mathematics higher than that of the grocer or housekeeper. They said that mathematics had trained their minds, but they did not need it in their profession. There is no profession which so much requires a man to have the mathematical tool always ready for use on all sorts of problems, the mathematical habit of thought the one most exercised by him; and yet these men insist upon it that they can get all their calculations done for them by mathematicians paid so much a week. If they really thought about what they were saying, it would be an expression of the greatest contempt for all engineering computation and knowledge. He was pitchforked into works with no knowledge of mathematics, or dynamics, or physics, or chemistry, and, worse still, ignorant of the methods of study which a study of these things would have produced; into works where there was no man whose duty it was to teach an apprentice; and because he, one in a thousand, has been successful, he assures us that this pitchforking process is absolutely necessary for every young engineer. He forgets that the average boy leaves an English school with no power to think for himself, with a hatred for books, with less than none of the knowledge which might help him to understand what he sees, and he has learnt what is called mathematics in such a fashion that he hates the sight of an algebraic expression all his life after.

I do not want to speak of boys in general. I want only to speak of the boy who may become an engineer, and before speaking of his training I want to mention his essential natural qualification—that he really wishes to become an engineer. I take it to be a rule to which there are no exceptions that no boy ought to enter a profession—or, rather, to continue in a profession—if he does not love it. We all know the young man who thinks of engineering things during office hours and never thinks of them outside office hours. We know how his fond mother talks of her son as an engineer who, with a little more family influence and personal favour, and if there was not so much competition in the profession, would do so well. It is true, family influence may perhaps get such a man a better position, but he will never be an engineer. He is not fit even to be a hewer of wood and drawer of water to engineers. Love for his profession keeps a man alive to its interests all his time, although, of course, it does not prevent his taking an interest in all sorts of other things as well; but it is only a professional problem that warms him through with enthusiasm. I think we may assume that there never yet was an engineer worth his salt who was not fond of engineering, and so I shall speak only of the education of the young man who is likely to be fond of engineering.

How are we to detect this fondness in a boy? I think that if the general education of all boys were of the rational kind which I shall presently describe, there would be no great difficulty; but as the present academic want of system is likely to continue for some time, it is well to consider things as they are. Mistakes must be made, and the parent who tries during the early years of his offspring to find out by crafty suggestion what line his son is likely to wish to follow will just as probably do evil by commission as the utterly careless parent is likely to do evil by omission. He is like the botanical enthusiast who digs up plants to see how they are getting on. But in my experience the Anglo-Saxon boy can stand a very great deal of mismanagement without permanent hurt, and it can do no kind of boy any very great harm to try him on engineering for a while. Even R. L. Stevenson, whose father seems to have been very persistent indeed in trying to make an engineer of him against his will, does not seem, to a Philistine like myself, to have been really hurt as a literary man through his attendance on Fleeming Jenkins' course at Edinburgh—on the contrary, indeed. It may be prejudice, but I have always felt that there is no great public person of whom I have ever read who would not have benefited by the early training which is suitable for an engineer. I am glad to see that Mr. Wells, whose literary fame, great as it is, is still on the increase, distinguishes the salt of the earth or saviours of society from the degraded, useless, luxurious, pleasure-loving people doomed to the abyss by their having had the training of engineers and by their possessing the engineer's methods of thinking.

It may be that there are some boys of great genius to whom all physical science or application of science is hateful. I have been told that this is so, and if so I still think that only gross mismanagement of a youthful nature can have produced such detestation. For such curious persons, engineering experience is, of course, quite unsuitable. I call them "curious" because every child's education in very early years is one in the methods of the study of physical science; it is Nature's own method of training, which proceeds successfully until it is interfered with by ignorant teachers who check all power of observation and the natural desire of every boy to find out things for himself. If he asks a question, he is snubbed; if he observes Nature as a loving student, he is said to be lazy and a dunce, and is punished as being neglectful of school work. Unprovided with apparatus, he makes experiments in his own way, and he is said to be destructive and full of mischief. But however much we try to make the wild ass submit to bonds and the unicorn to abide by the crib, however bullied and beaten into the average schoolboy type, I cannot imagine any healthy boy suffering afterwards by part of a course of study suitable for engineers, for all such study must follow Nature's own system of observation and experiment. Well, whether or not a mistake has been made, I shall assume the boy to be likely to love engineering, and we have to consider how he ought to be prepared for his profession.

I want to say at the outset that I usually care only to speak of the average boy, the boy usually said to be stupid, ninety-five per cent. of all boys. Of the boy said to be exceptionally clever I need not speak much. Even if he is pitchforked into works immediately on leaving a bad school, it will not be long before he chooses his own course of study and follows it, whatever course may have been laid down for him by others. I recollect that when in 1863 I attended an evening class held in the Model School, Belfast, under the Science and Art Department, on Practical Geometry and Mechanical Drawing, there was a young man attending it who is now well known as the Right Honourable William J. Pirrie. He had found out for himself that he needed a certain kind of knowledge if he was to escape from mere rule-of-thumb methods in shipbuilding work; it could at that time be obtained nowhere in the North of Ireland except at that class, and of course he attended the class. For forty two years the Science and Art Department, which has recently doubled its already great efficiency, has been giving chances of this kind to every clever young man in the country, from long before any Physical Science was taught in any English public school.[1] The one essential thing for the exceptional boy is that he shall find within his reach chances to take advantage of; chances of learning; chances of practice; and, over and above all, chances of meeting great men. It takes me off my subject a little, but I should like here to illustrate this matter from my own personal experience.

I had already been an apprentice for four years at the Lagan Foundry when I entered Queen's College for a course of Civil Engineering. I suppose that there never was on this earth a college so poorly equipped for a course of engineering study. Even the lecture room—this lecture room in which you are now sitting—was borrowed from the Physics Professor. There was a narrow passage, ironically called a "Drawing Room," and this was the only space reserved for engineering in a town whose engineering work was even then very important. There were some theodolites and levels and chains for surveying, but nothing else in the way of apparatus. But there was as Professor a man of very great individuality; he acted as President of this Section twenty-eight years ago. I can hardly express my obligations to Prof. James Thomson. It was my good fortune to be a pupil both of this great man and of his younger brother, Lord Kelvin, as well as of Dr. Andrews. It is not because these three men were born in Belfast that we here call them great. It is not because Tait, late of Edinburgh, and

[1] I once stated that my workshop at Clifton College in 1871 was the first school workshop in England. I understand that this is a mistake; there had been a workshop at Rossall for some years. But I believe I am right in saying that my physical laboratory at Clifton was the first school laboratory in England. These ideas were not mine; they were those of the Headmaster, now the Bishop of Hereford.

Purser, now the President of Section A, were professors at this College that we call them great. All the scientific men of the world are agreed to call these men very great indeed. To come in contact with any of them, even for a little while, as a student, altered for ever one's attitude to Nature. It was not that they gave us information, knowledge, facts. The syllabuses of their courses of study were nothing like so perfect as that of the smallest German polytechnic. And yet if a youth with a liking for physical science had gone to a German Gymnasium to the age of nineteen, and had become a walking encyclopædia on leaving one's polytechnic at the age of twenty-four, the course of that life-study would not have done for him as much good as was done by a month's contact with one of these men. People call it "personal magnetism" and think there is something occult about it. In truth, they revealed to the student that he himself was a man, that mere learning was unimportant, that one's own observation of some common phenomenon might lead to important results unknown to the writers of books. They made one begin to think for oneself for the first time. Let me give an example of how the thing worked.

James Thomson was known to me as the son of the author of my best mathematical books, but more particularly as the man who had first used Carnot's principle in combination with the discovery of Joule, and I often wondered why Rankine and Clausius and Kelvin got all the credit of the discovery of the second law of thermodynamics. Men think of this work of his merely as having given the first explanation of regelation of ice and the motion of glaciers. He was known to me as the inventor of the Thomson Turbine and Centrifugal Pump and Jet Pump. His name was to be found here and there in all my text-books, always in connection with some thoroughly well-worked-out investigation, as it is to be found in all good text-books now; for wherever he left a subject, there that subject has remained until this day; nobody has added to it or found a mistake in it. He was to me a very famous man, and yet he treated me as a fellow-student. One of his early lectures was about flowing water, and he told us of a lot of things he had observed, which also I had observed without much thought; and he showed how these simple observations completely destroyed the value of everything printed in every text-book on the subject of water flowing over gauge-notches, even in the otherwise very perfect Rankine. I felt how stupid I had been in not having drawn these conclusions myself, but in truth till then I had never ventured for a moment to criticise anything in a book. I have been a cautious critic of all statements in text-books ever since. If any engineer wants to read what is almost the most instructive paper that has ever been written for engineers, let him refer to the latest paper written by James Thomson on this subject.[1] The reasoning there given was given to me in lectures in this very room in 1868, and had been given to students for many years previous.

Again, soon afterwards, he let me see that although I had often looked at the whirlpool in a basin of water when the central bottom hole is open, and although I had read Edgar Allen Poe's mythical description of the Maëlstrom, I had been very much too careless in my observation. Among other things, Thomson had observed that particles of sand gradually passed along the bottom towards the hole. When he found out the cause of this, it led him at once to several discoveries of great importance. Indeed, the study of this simple observation gave rise to all his work on (1) What occurs at bends of pipes and channels, and why rivers in alluvial plains bend more and more; (2) The explanation of the curious phenomena that accompany great forest fires; (3) The complete theory of the great wind circulation of the earth, published in its final form as the Bakerian Lecture of the Royal Society in 1892.

But why go on? He taught me to see that the very commonest phenomenon had still to reveal important secrets to the understanding eye and brain, and that no man is a true student unless he is a discoverer. And so it was with Kelvin and Andrews. Their names were great before the world, and yet they treated one as a fellow-student. Is any expenditure of money too large if we can obtain great men like these for our Engineering Colleges? Money is wanted for apparatus and more particularly for men, and we spend what little we have on bricks and mortar!

The memory of a man so absolutely honest as Prof. James Thomson was compels me to say here that I was in an exceptionally fit state to benefit by contact with him, for I hungered for scientific information.[1] I do not think that there was so much benefit for the average student whose early education had almost unfitted him for engineering studies. To work quantitatively with apparatus is good for all students, but it is absolutely necessary for the average student, and, as I said before, there was no apparatus. Also the average student cannot learn from lectures merely, but needs constant tutorial teaching, and the Professor had no assistant.

Anybody who wants to know what kind of engineering school there ought to be in such a college as this can see excellent specimens (sometimes several in one town) in Glasgow, Birmingham, Liverpool, London, Manchester, Leeds, Bristol, Nottingham, Edinburgh and other great cities. There the fortunate manufacturers have given many hundreds of thousands of pounds for instruction in applied science (engineering). In America the equipment of such schools is much more thorough and there are large staffs of teachers, for fortunate Americans have contributed tens of millions of pounds for this kind of assistance to the rising generation. Germany and Switzerland compete with America in such preparation for supremacy in manufacture and engineering, and nearly every country in the world is more and more recognising its importance as they see the great inventions of Englishmen like Faraday and Perkin and Hughes and Swan developed almost altogether in those countries which believe in education. Even one hundred thousand pounds would provide Queen's College, Belfast, with the equipment of an engineering school worthy of its traditions and position, and Belfast is a city in which many large business fortunes have been made.

It is interesting to note that the present arrangements of the Royal University of Ireland, with which this College is affiliated, are such that most of the successful graduates in engineering of Queen's University would now be debarred from taking the degree. Even in London University, Latin is not a compulsory subject for degrees in science; Ireland has taken a step backwards towards the Middle Ages at the very time when other countries are stepping forward.

Well equipped schools of applied science are getting to be numerous, but I am sorry to say that only a few of the men who leave them every year are really likely to become good engineers. The most important reason for this is that the students who enter them come usually from the public schools; they cannot write English; they know nothing of English subjects; they do not care to read anything except the sporting news in the daily papers; they cannot compute; they know nothing of natural science; in fact, they are quite deficient in that kind of general education which every man ought to have.

I am not sure that such ignorant boys would not benefit more by entering works at once than by entering a great engineering school. They cannot follow the College courses of instruction at all, in spite of having passed the entrance examination by cramming. Whereas after a while they do begin to understand what goes on in a workshop; and if they have the true engineer's spirit, their workshop observation will greatly correct the faults due to stupid schoolwork.[2]

Perhaps I had better state plainly my views as to what general education is best for the average English boy. The public schools of England teach English through Latin, a survival of the time when only special boys were taught at all, and when there was only one language in which people wrote. Now the *average* boy is also taught Latin, and when he leaves school for the army or any other pursuit open

[1] Brit. Assoc. Report, 1876, pp. 243–266.

[1] Some of our most successful graduates went direct to works from the Model School, Belfast, and afterwards attended this College. No school in the British Islands could have given better the sort of general education which I recommend for all boys. English subjects were especially well taught, so that boys became fond of reading all manner of books. There were good classes in freehand and machine drawing, classes in chemistry and physics (at that time I believe that there were no such classes in any English public school), and the teaching of mathematics was good. Some of the masters started classes also under the Science and Art Department. Some of the masters had much individuality, and there was no outside examination to restrain it; there was only encouragement. Evidence has been given before a committee of the London School Board as to the excellence of the teaching at this school forty years ago. Foreign languages were not in the regular curriculum, but they could be studied by boys inclined that way; and in my opinion this is the position that all languages other than English ought to take in any British school. With such preparation a boy was eager and able to understand what went on in engineering works from his first day there.

[2] When I was young I remember that there were many agricultural colleges in Ireland; they have all but one been failures. Why? Because the entering pupils were not prepared by early education to understand the instruction; this had done as much as possible to unfit them.

to average boys he cannot write a letter, he cannot construct a grammatical sentence, he cannot describe anything he has seen. The public-school curriculum is always growing, and it is never subtracted from or rearranged. There is one subject which ordinary schoolmasters can teach well—Latin.[1]

The other usual nine subjects have gradually been added to the curriculum for examination purposes; they are taught in water-tight compartments—or, rather, they are only crammed, and not taught at all. Our school system resembles the ordinary type of old-established works, where gradual accretion has produced a higgledy-piggledy set of shops which one looks at with stupefaction, for it is impossible to get business done in them well and promptly, and yet it seems impossible to start a reform anywhere. What is wanted is an earthquake or a fire—a good fire—to destroy the whole works and enable the business to be reconstructed on a consistent and simple plan. And for much the same reason our whole public-school system ought to be "scrapped." What we want to see is that a boy of fifteen shall be fond of reading, shall be able to compute and shall have some knowledge of natural science; or, to put it in another way, that he shall have had mental training in the study of his own language, in the experimental study of mathematics and in the methods of the student of natural science. Such a boy is fit to begin any ordinary profession, and whether he is to enter the Church, or take up medicine or surgery, or become a soldier, every boy ought to have this kind of training. When I have advocated this kind of education in the past I have usually been told that I was thinking only of boys who intend to be engineers; that it was a specialised kind of instruction. But this is very untrue. Let me quote from the recommendations of the 1902 Military Education Committee (Report, p. 5):—

[1] Only one subject—Latin—is really educational in our schools. I do not mean that the average boy reads any Latin author after he leaves school, or knows any Latin at all ten years after he leaves school. I do not mean that his Latin helps him even slightly in learning any modern language, for he is always found to be ludicrously ignorant of French or German, even after an elaborate course of instruction in these languages. I do not mean that his Latin helps him in studying English, for he can hardly write a sentence without error. I do not mean that it makes him fond of literature, for of ancient literature or history he never has any knowledge except that Cæsar wrote a book for the third form, and on English literature his mind is a blank. But I do mean that as the ordinary public-school master is really able to give a boy easy mental exercises through the study of Latin, this subject is in quite a different position from that of the others. If any proof of this statement is wanted, it will be found in the published utterances of all sorts of men—military officers, business men, lawyers, men of science, and others—who, confessedly ignorant of "the tongues," get into a state of rapture over their school experiences and the efficiency of Latin as a means of education. All this comes from the fact, which schoolboys are sharp enough to observe, that English schoolmasters can teach Latin well, and they do not take much interest in teaching anything else. It is a power inherited from the Middle Ages, when there really was a simple system of education. I ask for a return to simplicity of system. English (the King's English; I exclude Johnsonese) is probably the richest, the most complex language, the one most worthy of philologic study; English literature is certainly more valuable than any ancient or modern literature of any one other country yet admiration for it among learned Englishmen is wonderfully mixed with patronage and even contempt. At present, is there one man who can teach English as Latin is taught by nearly every master of every school? Just imagine that English could be so taught by teachers capable of rising to the level of our literature!

I have often to give advice to parents. I find the average parent exceedingly ignorant of his son's character or inclinations or ability. He pays a schoolmaster handsomely for taking his son off his hands except during holidays. During the holidays, so terrible to a parent, he sees his son as little as possible. One question always asked is: Do you think it better to have "theoretical" instruction (they always call it by this absurd name) before or after an actual apprenticeship in works? Of course, such a question cannot be answered offhand. You tell the parent, to his great astonishment, that you must see the boy himself. When at length you see him, the chances are that you will find him to be what the schoolmasters are making of all our average boys. No part of his school work has been a pleasure to him, and, although he has had to work hard at his books, not one of the above three powers is his—power to use books and to write his own language; the language of his nurse, his mother, his mistress that is to be, his enemies and friends; the only language in which he thinks—power to compute and a liking for computation—power to understand a little of natural phenomena. Honestly I practically never find that such a boy has had any education at all except what he has obtained at home or from his school companions or from his sports. Even his sports are to keep him healthy of body only and not at all to cultivate his mental powers. Those old games like "Prisoners' Base," which really developed in a wonderful way not only all the muscles of the body, but also the thinking power, are scorned in the public schools. Think now how such a boy is handicapped if we pitchfork him into works where it is nobody's duty to teach him anything, or send him to college, where he cannot understand the lectures. Of course, if he is very eager to be an engineer he will, by book or by crook, get to understand things. I have met some such men—clever, successful engineers in spite of all sorts of adverse circumstances—but the best of them are willing to admit that they are, and have always been, greatly hurt by the absence of the three powers which I have specified. And if this has been so in the past, when the scientific principles underlying engineering have been simple, how much more so is it now, when every new discovery in physics is producing new branches of engineering!

"The fifth subject which may be considered as an essential part of a sound general education is experimental science; that is to say, the science of physics and chemistry treated experimentally. As a means of mental training, and also viewed as useful knowledge, this may be considered a necessary part of the intellectual equipment of every educated man, and especially so of the officer, whose profession in all its branches is daily becoming more and more dependent on science." When statements of this kind have been made by some of us in the past, nobody has paid much attention; but I beg you to observe that the headmaster of Eton and the headmaster of St. Paul's School are two of the members of the important Committee who signed this recommendation, and it is impossible to ignore it. Last year, for the first time, the President of the Royal Society made a statement of much the same kind, only stronger, in his annual address. I am glad to see that the real value of education in physical science is now appreciated; that mere knowledge of scientific facts is known to be unimportant compared with the production of certain habits of thought and action which the methods of scientific study usually produce.

As to English, the Committee say: "They have no hesitation in insisting that a knowledge of English,[1] as tested by composition, together with an acquaintance with the main facts of the history and geography of the British Empire, ought in future to hold the *first* place in the examination and to be exacted from all candidates." The italics are mine. It will be noticed that they say nothing about the practical impossibility of obtaining teachers. As to mathematics, the Committee say: "It is of almost equal importance that every officer should have a thorough grounding in the elementary part of mathematics. But they think that elementary mechanics and geometrical drawing, which under the name of practical geometry is now often used as an introduction to theoretical instruction, should be added to this part of the examination, so as to ensure that at this stage of instruction the practical application of mathematics may not be left out of sight." As Sir Hugh Evans would have said, "It is a very discretion answer—the meaning is good"; but I would that the Committee had condemned abstract mathematics for these army candidates altogether.

This report appears in good time. It would be well if Committees would sit and take evidence as to the education of men in the other professions entered by our average boys. It is likely that when an authoritative report is prepared on the want of education of clergymen, for example, exactly the same statements will be made in regard to the general education which ought to precede the technical training; but perhaps a reference may be made in the report to the importance of a study of geology and biology as well as physical science. Think of the clergyman being able to meet his scientific enemies in the gate!

Thanks mainly to the efforts of a British Association Committee, really good teaching of experimental science is now being introduced into all public schools, in spite of most persistent opposition wearing an appearance of friendliness. In consequence, too, of the appointment of a British Association Committee last year, at what might be called the psychological moment, a great reform has already begun in the teaching of mathematics.[2] Even in the regulations for the Oxford Locals for 1903, Euclid is repudiated. It seems probable that at the end of another five years no average boy of fifteen years of age will have been compelled to attempt any abstract reasoning about things of which he knows nothing; he will be versed in experimental mathematics, which he may or may not call mensuration; he will use logarithms, and mere multiplication and division will be a joy to him; he will have a working power with algebra and sines and cosines; he will be able to tackle at once any curious new problem which can be solved by squared

[1] This Committee recommends for the Woolwich and Sandhurst candidates a reform that has already been carried out by London University. No dead language is to be compulsory, but unfortunately some language other than English is still to be compulsory. Those boys, of whom there are so many, who dislike and cannot learn another language are still to be labelled "uneducated." Must there, then, be national defeat and captivity before our chosen race gives up its false academic gods? We think of education in the most slovenly fashion. The very men who say that *utility* is of no importance are the men who insist on the usefulness of a knowledge of French or German. They say that a man is illiterate if he knows only English, although he may be familiar with all English literature and with other literatures through translations. The man who has passed certain examinations in his youth and never cares to read anything is said to be educated. The men of the city of the Violet Crown, were they not educated? And did they know any other than their own language?

[2] Discussion last year and report of Committee, published by Macmillan.

paper; and he will have no fear of the symbols of the infinitesimal calculus. When I insist that a boy ought to be able to compute, this is the sort of computation that I mean. Five years hence it will be called "elementary mathematics." Four years ago it was an unorthodox subject called "practical mathematics," but it is establishing itself in every polytechnic and technical college and evening or day science school in the country. Several times I have been informed that on starting an evening class, when plans have been made for a possible attendance of ten or twenty students, the actual attendance has been 200 to 300. Pupils may come for one or two nights to a class on academic mathematics, but then stay away for ever; a class in practical mathematics maintains its large numbers to the end of the winter.[1]

Hitherto the average boy has been taught mathematics and mechanics as if he were going to be a Newton or a Laplace; he learnt nothing and became stupid. I am sorry to say that the teaching of mechanics and mechanical engineering through experiment is comparatively unknown. Cambridge writers and other writers of books on experimental mechanics are unfortunately ignorant of engineering. University courses on engineering—with one splendid exception, under Prof. Ewing at Cambridge—assume that undergraduates are taught their mechanics as a logical development of one or two axioms; whereas in many technical schools under the Science and Art Department, apprentices go through a wonderfully good laboratory course in mechanical engineering. We really want to give only a few fundamental ideas about momentum and the transformations of energy and the properties of materials, and to give them from so many points of view that they become part of a student's mental machinery, so that he uses them continually. Instead of giving a hundred labour-saving rules which must be forgotten, we ought to give the one or two ideas which a man's commonsense will enable him to apply to any problem whatsoever and which cannot be forgotten. A boy of good mathematical attainments may build on this experimental knowledge afterwards a superstructure more elaborate than Rankine or Kelvin or Maxwell ever dreamt of as being possible. Every boy will build some superstructure of his own.

I must not dwell any longer on the three essential parts of a good general education which lead to the three powers which all boys of fifteen ought to possess; power to use books and to enjoy reading; power to use mathematics and to enjoy its use; power to study Nature sympathetically. English Board School boys who go to evening classes in many technical schools after they become apprentices are really obtaining this kind of education. The Scotch Education Board is trying to give it to all boys in primary and secondary schools. It will, I fear, be some time before the sons of well-to-do parents in England have a chance of obtaining it.

When a boy or man of any age or any kind of experience enters an engineering college and wishes to learn the scientific principles underlying a trade or profession, how ought we to teach him? Here is the reasonable general principle which Profs. Ayrton and Armstrong and I have acted upon, and which has so far led us to much success. Whether he comes from a bad or a good school, whether he is an old or young boy or man, approach his intelligence through the knowledge and experience he already possesses. This principle involves that we shall compel the teacher to take the pupil's point of view[2] rather than the pupil the teacher's; give the student a choice of many directions in which he may study; let lectures be rather to instruct the student how to teach himself than to teach him; show the student how to learn through experiment and how to use books, and, except for suggestion and help when asked for, leave him greatly to himself. If a teacher understands the principle he will have no difficulty in carrying it out with any class of students. I myself prefer to have students of very different qualifications and experience in one class because of the education that each gives to the others. Usually, however, except in evening classes, one has a set of boys coming from much the same kind of school, and, although perhaps differing considerably as to the places they might take in an ordinary examination, really all of much the same average intelligence. Perhaps I had better describe how the principle is carried out in one case—the sons of well-to-do parents such as now leave English schools at about fifteen years of age.

It was for such boys that the courses of instruction at the Finsbury Technical College (the City and Guilds of London Institute) were arranged twenty-two years ago. It was attempted to supply that kind of training which ought already to have been given at school, together with so much technical training as might enable a boy at the end of a two years' course to enter any kind of factory where applied science was important, with an observing eye, an understanding brain and a fairly skilful hand. The system, in so far as it applies to various kinds of mechanical engineering, will be found described in one of a small collection of essays called "England's Neglect of Science," pp. 57–67.[1] I am sure that any engineer who reads that description will feel satisfied that it was the very best course imaginable for the average boy of the present time. A boy was taught how he must teach himself after he entered works. If after two or three years in the works he cared to go for a year or so to one of the greater colleges, or did not so care, it was assumed that he had had such a training as would enable him to choose the course which was really the best for him.

Old Finsbury students are to be found everywhere in important posts. The experiment has proved so successful that every London Polytechnic, every Municipal Technical School in the country has adopted the system, and in the present state of our schools I feel sure that all important colleges ought to adopt the Finsbury system. It hardly seems appropriate to apply the word "system" to what was so plastic and uncrystallised and had nothing to do with any kind of ritual.

The Professors were given a free hand at Finsbury, and there were no outside examiners. I need not dwell upon the courses in Chemistry and Physics; some critics might call the subjects *Rational* Chemistry and Applied Physics; they were as different from all other courses of study in these subjects as the courses on Rational Mathematics and Mechanics differed from all courses elsewhere. The course on Mechanics was really one on Mechanical Engineering. There were workshops in wood and iron, not to teach trades, but rather to teach boys the properties of materials. There were a steam-engine and a gas-engine, and shafting and gearing of many kinds, and dynamos which advanced students in turn were allowed to look after under competent men. There was no machine which might not be experimented with occasionally. Elementary and advanced courses of lectures were given; there was an elaborate system of tutorial classes, where numerical and squared paper exercise work was done; there were classes in experimental plane and solid geometry, including much graphical calculation; boys were taught to make drawing-office drawings in pencil only, and tracings and blue prints, such as would be respected in the workshop, and not the ordinary drawing-class drawings, which cannot be respected anywhere; but the most important part of the training was in the Laboratory, in which every student worked, making quantitative experiments. An offer of a 100-ton testing-machine for that laboratory was made, but refused; the advanced students usually had one opportunity given them of testing with a large machine, but not in their own laboratory. I consider that there is very little educational value in such a machine; the student thinks of the great machine,[2] and not of

[1] To many men it will seem absurd that a real working knowledge of what is usually called higher mathematics, accompanied by mental training, can be given to the average boy. In the same way it seemed absurd 500 years ago that power to read and write and cipher could be given to everybody. These general beliefs of ours are very wonderful.

[2] Usually it is assumed that there is only one line of study. In mathematics it is assumed that a boy has the knowledge and power and past experience and leisure of an Alexandrian philosopher. In mechanics we assume the boy to be fond of abstract reasoning, that he is a good geometrician who can do the most complex things in geometrical conics, but cannot possibly take in the simplest idea of the calculus.

[1] The ideas in this Address have been put forward many times by Prof. Ayrton and myself. See the following, among other publications:—"England's Neglect of Science" (Fisher Unwin); "Practical Mechanics," 1881 (Cassell); "Applied Mechanics," 1897 (Cassell); "The Steam Engine, &c.," 1898 (Macmillan); "The Calculus for Engineers," 1897 (Arnold); Recent Syllabuses and Examination Papers of the Science and Art Department in Subjects I., VII., V*p*. and XXII.; Summary of Lectures on Practical Mathematics (Board of Education); The Work of the City and Guilds Central Technical College (*Journal* of the Society of Arts, July 9, 1897): Inaugural Lecture at Finsbury, 1879; Address at the Coventry Technical Institute, February, 1898: "Education of an Electrical Engineer" (*Journal* of the Society of Telegraph Engineers and of Electricians, September, 1882); Presidential Address, Institution of Electrical Engineers, January, 1892; "The Best Education for an Engineer" (NATURE), October 12, 1899; Address at a Drawing-room Meeting, March, 1887.

[2] These great testing-machines, so common in the larger colleges, seem to have destroyed all idea of scientific experiment. There is so much that the engineer wants to know, and yet laboratory people are persistently and lazily repeating old work suggested and begun by engineers of sixty years ago. For example, men like Fairbairn and Robert Napier would long ago have found out the behaviour of materials under combined stresses. We do not even know the condition of strength of iron or steel in a twisted shaft which is also a beam. The theory of strength of a gun or thick tube under

the tiny specimen. Junior students loaded wires and beams, or twisted things with very visible weights, and saw exactly what was happening, or they studied vibrating bodies. Many hours were devoted to experiments on a battered, rusty old screw-jack, or some other lifting-machine, its efficiency under many kinds of load being determined, and students studied their observations using squared paper, as intently as if nobody had ever made such experiments before. There was one piece of apparatus, an old fly-wheel bought at a rag and-bone shop, to which kinetic energy was given by a falling weight, which, I remember, occupied the attention of four white-headed directors of Electric Companies in 1882 (evening students) for many weeks. A casual first measurement led on to corrections for friction and stiffness of a cord, and much else of a most interesting kind. At the end of six weeks these gentlemen had gained a most thorough computational acquaintance with every important principle of mechanics, a knowledge never to be forgotten. They had also had a revelation such as comes to the true experimenter—but that is too deep a subject.

Perhaps teachers in the greater colleges will smile in a superior way when they hear of this kind of experimental mechanics being called engineering laboratory work. True it was elementary mechanics; but is not every principle which every engineer constantly needs called a mere elementary principle of mechanics by superior persons? I find that these elementary principles are very much unknown to men who have passed through elaborate mathematical studies of mechanics. Students found out in that laboratory the worth of formulæ; they gained courage in making calculations from formulæ, for they had found out the extent of their own ignorance and knowledge.

I have never approved of elaborate steam-engines got up for students' laboratory exercise-work. A professor who had devoted much thought for a year to the construction of such a four-cylinder engine showed a friend how any one or any two or any three or all four cylinders, with or without jacketing, could be used in all sorts of ways. The friend ventured to say: "This engine will be used just once and never after." The professor was angry, but his friend proved to be right. The professor made experiments with it once himself with a few good students. Unfortunately, it was not a sufficiently elaborate investigation for publication. Afterwards he never had time personally to superintend such work; his assistants were busy at other things; his students could not be trusted with the engine by themselves, and to this day it stands in the laboratory a beautiful but useless piece of apparatus. At Finsbury there was an excellent one-cylinder engine with vaporising condenser. It drove the workshops and electric generators. On a field-day it drove an electric generator only, and perhaps thirty students made measurements. Each of them had already acted as stoker and engine-driver, as oiler and tester of the machinery, lighting fires, taking indicator diagrams, weighing coals, opening and closing cocks from seven in the morning to ten at night, so that everything was well known to him. They maintained three different steady loads for trials of three hours each. They divided into groups, one from each group ceasing to take a particular kind of observation every ten minutes and removing to another job. All watches were made to agree, and each student noted the time of each observation. These observations were:—Taking indicator diagrams, checking the speed indicator, taking temperature of feed-water, quantity of feed by meter (the meter had been carefully checked by gauge-notch, and every other instrument used by us had been tested weeks before), taking the actual horse-power passing through a dynamometer coupling on the shaft, taking boiler and valve-chest pressures and vacuum pressures on the roof and in the engine-room, weighing coals (the calorific value had already been tested), taking the horse-power given out by the dynamo, counting the electric lamps in use, and so on. Each student was well prepared beforehand. During the next week he reduced his own observations, and some of the results were gathered on one great table. One lesson that this taught could never be forgotten—how the energy of one pound of coal was disposed of. So much up the chimney or by radiation from boiler or steam-jacket and pipes; in condensation in the cylinder; to the condenser; in engine friction; in shaft friction, &c. I cannot imagine a more important lesson to a young engineer than this one taught through a common working engine. The students had the same sort of experience with a gas-engine. I need hardly say how important it was that the Professor himself should take charge of the whole work leading up to, during, and after such a field-day.

The difficulty about all laboratory exercise work worth the name is that of finding demonstrators and assistants who are wise and energetic. Through foolishness and laziness the most beautiful system becomes an unmeaning routine, and the more smoothly it works the less educational it is. In England just now the curse of all education is the small amount of money available for the wages of teachers—just enough to attract mediocre men. I have been told, and I can easily imagine, that such men have one talent over-developed, the talent for making their job softer and softer, until at length they just sit at a table, maintaining discipline merely by their presence, answering the questions of such students as are earnest enough to come and worry them. In such cases it is absolutely necessary to periodically upset their clockwork arrangements. After such an artificial earthquake one might be reminded of what occurred at the pool of Bethesda, whose waters had their healing property restored when the angel came down and troubled them. But for a permanently good arrangement there ought to be very much higher wages all round in the teaching profession.

No kind of engineering has developed so rapidly as the electrical. Why, it was at the meeting here in Belfast twenty-eight years ago (I remember, for I was a Secretary of Section A that year, and took the machine to pieces afterwards in Lord Kelvin's laboratory) that there was exhibited for the first time in these islands a small Gramme machine. This handmaid of all kinds of engineering is now so important that every young engineer may be called uneducated who has not had a training in that kind of mechanical engineering which is called electrical engineering. Prof. Ayrton's laboratory at Finsbury is the model copied by every other electrical engineering laboratory in the world. He and I had the same notions; we had both been students of Lord Kelvin; we had worked together in Japan since 1875; but whereas I was trying to make my system of teaching mechanical engineering replace an existing system, or want of system, there was no existing system for his to replace. Thus it will be found that in every electrical engineering laboratory the elementary principles are made part of a pupil's mental machinery by many quantitative experiments, and nobody suggests that it is mere elementary physics which is being taught—a suggestion often enough made about the work in my mechanical laboratory. When students know these elementary principles well, they can apply their mathematics to the subject. As they advance in knowledge they are allowed to find out by their own experiments how their simple theories must be made more complex in real machines. Their study may be very complete, but, however much mathematics and graphical calculation may come in, their designs of electrical machinery are really based upon the knowledge acquired by them in the electrical and mechanical laboratories.

The electrical engineer has an enormous advantage over other engineers; everything lends itself to exact calculation, and a completed machine or any of its parts may be submitted to the most searching electrical and magnetic tests, since these tests, unlike those applied by other engineers, do not destroy the body tested. But for this very reason, as a finished product, the electrical engineer cannot have that training in the exercise of his judgment in actual practical work after he leaves a college that some other engineers must have. In tunnelling, earthwork and building, in making railways and canals, the engineer is supremely dependent on the natural conditions provided for him, and these conditions are never twice the same. There are no simple laws known to us about the way in which sea and river currents will act upon sand and gravel, and engineers who have had to do with such problems are continually appealing to Nature, continually making observations and bringing to bear upon their work all the knowledge and habits of thought that all their past experience has given them. I do not know that there is any job which a good teacher would have greater

hydraulic pressure is no clearer now than it was fifty years ago. The engineer asks for actual information derived from actual trial, and we offer him the "cauld kail het again" stuff falsely called "theoretical," which is found in all the text-books (my own among others). These great colleges of university rank ought to recognise that it is their duty to increase knowledge through the work of their advanced students. The duty is not neglected in the electrical departments of some of the colleges. Perhaps the most instructive reference is to the work done at the Central Technical College of the City and Guilds Institute at South Kensington, as described by Prof. Ayrton in some of the papers already referred to. I cannot imagine a better development of the Finsbury idea in the work of the highest kind of Engineering College.

pleasure in undertaking than the arrangement of a laboratory in which students might study for themselves such problems as come before railway, canal, river, harbour and coast-protection engineers; there is no such laboratory in existence at the present time, and in any case it could only be of use in the way of mere suggestion to an engineer who had already a good knowledge of his profession.

It was a curious illustration of mental inertia that the usual engineering visitor, even if he was a professor of engineering, always seemed to suppose that the work done at Finsbury was the same as that done in all the great engineering colleges. As a matter of fact, no subject was taught there in the same manner as it was taught elsewhere.[1]

Most of the students were preparing for electrical or mechanical engineering, and therefore we thought it important that nearly every professor or demonstrator or teacher should be an engineer. I know of nothing worse than that an engineering student should be taught mathematics or physics or chemistry by men who are ignorant of engineering, and yet nothing is more common in colleges of applied science.[2] The usual courses are only suitable for men who are preparing to be mere mathematicians, or mere physicists, or mere chemists. Each subject is taken up in a stereotyped way, and it is thought quite natural that in one year a student shall have only a most elementary knowledge of what is to the teacher such a great subject. The young engineer never reaches the advanced parts which might be of use to him: he is not sufficiently grounded in general principles; his whole course is only a preliminary course to a more advanced one which there is no intention of allowing him to pursue, and, not being quite a fool, he soon sees how useless the thing is to him. The Professor of Chemistry ought to know that until a young engineer can calculate exactly by means of a principle, that principle is really unknown to him. For example, take the equation supposed to be known so well,

$$2H_2 + O_2 = 2H_2O.$$

It is never understood by the ordinary elementary chemical student who writes it down so readily. Every one of the six cunning ways in which that equation conveys information ought to be as familiar to the young engineer as they are, or ought to be, to the most specialised chemist. Without this he cannot compute in connection with combustion in gas and oil engines and in furnaces. But I have no time to dwell on the importance of this kind of exact knowledge in the education of an engineer.

Mathematics and physics and chemistry are usually taught in watertight compartments, as if they had no connection with one another. In an engineering college this is particularly bad. Every subject ought to be taught through illustrations from the professional work in which a student is to be engaged. An engineer has been wasting his time if he is able to answer the questions of an ordinary examination paper in chemistry or pure mathematics. The usual mathematical teacher thinks most of those very parts of mathematics which to an ordinary man who wants to *use* mathematics are quite valueless, and those parts which would be altogether useful and easy enough to understand he never reaches; and, as I have said, so it is also in chemistry. Luckily, the physics professor has usually some small knowledge of engineering; at all events he respects it. When the pure mathematician is compelled to leave the logical sequence which he loves to teach mechanics, he is apt scornfully to do what gives him least trouble; namely, to give as "mechanics" that disguised pure mathematics which forms ninety per cent. of the pretence of theory to be found in so many French and German books on machinery. As pure mathematical exercise work it is even meaner than the stupid exercises in school algebras; as pretended engineering it does much harm because a student does not find out its futility until after he has gone through it, and his enthusiasm for mathematics applied to engineering problems is permanently hurt. But how is a poor mathematical professor who dislikes engineering, feeling like Pegasus harnessed to a common waggon—how is he to distinguish good from evil? He fails to see how worthless are some of the books on "Theoretical Mechanics" written by mathematical coaches to enable students to pass examinations. An engineer teaching mathematics would avoid all futilities; he would base his reasoning on that experimental knowledge already possessed by a student; he would know that the finished engineer cannot hope to remember anything except a few general principles, but that he ought to be able to apply these, clumsily or not, to the solution of any problem whatsoever. Of course he would encourage some of his pupils to take up Thomson and Tait, or Rayleigh's "Sound," or some other classical treatise as an advanced study.[1]

Not only do I think that every teacher in an engineering college ought to have some acquaintance with engineering, but it seems to me equally important to allow a professor of engineering, who ought, above all things, to be a practical engineer, to keep in touch with his profession. A man who is not competing with other engineers in practical work very quickly becomes antiquated in his knowledge: the designing work in his drawing-office is altogether out of date; he lectures about old difficulties which are troubles no longer; his pupils have no enthusiasm in their work because it is merely academic and lifeless; even when he is a man distinguished for important work in the past his students have that kind of disrespect for his teaching which makes it useless to them. If there is fear that too much well-paid professional work will prevent efficiency in teaching, there is no great difficulty in applying a remedy.

One most important fact to be borne in mind is that efficient teachers cannot be obtained at such poor salaries as are now given. An efficient labourer is worthy of his hire; an inefficient labourer is not worthy of any hire, however small. Again, there is a necessity for three times as many teachers as are usually provided in England. The average man is in future to be really educated. This means very much more personal attention, and from thoughtful teachers. Is England prepared to face the problem of technical education in the only way which can lead to success, prepared to pay a proper price for the real article? If not, she must be prepared to see the average man remaining uneducated.

Advocacy of teaching of the kind that was given at Finsbury is often met by the opposition, not only of pure mathematicians and academic teachers, but I am sorry to say also of engineers. The average engineer not merely looks askance at, he is really opposed to the college training of engineers, and I think, on the whole, that he has much justification for his views. University degrees in engineering science are often conferred upon students who follow an academic course, in which they learn little except how to pass examinations. The graduate of to-day, even, does not often possess the three powers to which I have referred. He is not fond of reading, and therefore he has no imagination, and the idea of an engineer without imagination is as absurd as Teufelsdröch's notion of a cast-iron king. He cannot really compute, in spite of all his mathematics, and he is absurdly innocent of the methods of the true student of Nature. This kind of labelled scientific engineer is being manufactured now in bulk because there is a money value attached to a degree. He is not an engineer in any sense of the word, and does not care for engineering, but he sometimes gets employment in technical colleges. He is said to teach when he is really only impressing upon deluded pupils the importance of formulæ and that whatever is printed in books must be true. The real young engineer, caught in this eddy, will no doubt find his way out of it, for the healthy experience of the workshop will bring back his common-sense. For the average pupil of such graduates there is no help. If he enters works, he knows but little more than if he had gone direct from school. He is still without the three qualifications which are absolutely necessary for a young engineer. He is fairly certain to be a nuisance in the works and to try another profession at the end of his pupilage. But if it is his father's business he can make

[1] It is really ludicrous to see how all preachers on technical education are supposed by non thinking people to hold the same doctrine. The people asking for reform in education differ from one another more than Erasmus and Luther, and John of Leyden and Knipperdoling.

[2] At the most important colleges the usual professor or tutor is often ignorant of all subjects except his own, and he generally seems rather proud of this; but surely in such a case a man cannot be said to know even his own subject.

[1] One sometimes finds a good mathematician brought up on academic lines taking to engineering problems. But he is usually *stale* and unwilling to go thoroughly into these practical matters, and what he publishes is particularly harmful, because it has such an honest appearance. When we do get, once in forty years, a mathematician (Osborne Reynolds or Dr. Hopkinson) who has common-sense notions about engineering things, or a fairly good engineer (Rankine or James Thomson) who has a common-sense command of mathematics, we have men who receive the greatest admiration from the engineering profession, and yet it seems to me that quite half of all the students leaving our technical colleges ought to be able to exercise these combined powers if mathematics were sensibly taught in school and college. We certainly have had enough of good mathematicians meddling with engineering theory and of engineers with no mathematics wasting their time in trying to add to our knowledge.

a show of knowing something about it, and he is usually called an engineer.

Standardisation in an industry usually means easier and cheaper and better manufacture, and a certain amount of it must be good even in engineering, but when we see a great deal of it we know that in that industry the true engineer is disliked. I consider that in the scholastic industry there has been far too much standardisation. Gymnasien and polytechnic systems are standardised in Germany, and there is a tendency to import them into England; but in my opinion we are very far indeed from knowing any system which deserves to be standardised, and the worst we can copy is what we find now in Germany and Switzerland. What we must strive for is the discovery of a British system suiting the British boy and man. The English boy may be called stupid so often that he actually believes himself to be stupid; but of one thing we may be sure, he will find in some way or other an escape from the stupefying kind of school work to which the German boy submits. And if it were possible to make the average English boy of nineteen pass such a silly school-leaving examination as the German boy,[1] and to pass through a polytechnic, I am quite sure that there would be little employment among common-sense English engineers for such a manufactured article. But is it possible that British boys could be manufactured into such obedient academic machines, without initiative or invention or individuality, by teachers who are none of them engineers? No, we must have a British system of education. We cannot go on much longer as we have done in the past without engineering education, and, furthermore, it must be such as to commend itself to employers. Of my Finsbury students I think I may say that not one failed to get into works on a two or three years' engagement, receiving some very small wage from the beginning, and without paying a premium. To obtain such employment was obviously one test of fitness to be an engineer, because experienced men thought it impossible. One test of the system was the greater ease with which new men obtained employment in shops which had already taken some of our students. It is certainly very difficult to convince an employer that a college man will not be a nuisance in the shops. In Germany and France, and to a less extent in America, there is among employers a belief in the value of technical education. In England there is still complete unbelief. I have known the subscribers of money to a large technical college in England (the members of its governing board) to laugh, all of them, at the idea that the college could be of any possible benefit to the industries of the town. They subscribed because just then there was a craze for technical education due to a recent panic. They were ignorant masters of works (sons of men who had created the works), ignorant administrators of the college affairs and ignorant critics of their mismanaged college. I feel sure that if the true meaning of technical education were understood, it would commend itself to Englishmen. Technical education is an education in the scientific and artistic principles which govern the ordinary operations in any industry. It is neither a science nor an art, nor the teaching of a handicraft. It is that without which a master is an unskilled master; a foreman an unskilled foreman; a workman an unskilled workman; and a clerk or farmer an unskilled clerk or farmer. The cry for technical education is simply a protest against the existence of unskilled labour of all kinds.[2]

To have any good general system the employers must cooperate. Much of the training is workshop practice, and it cannot be too often said that this is not to be given in any college. The workshop in a college serves a quite different purpose. Now how may the practice best be given? I must say that I like the Finsbury plan very much indeed, but there are others. When I attended this college in winter I was allowed to work in the Lagan Foundry in summer. In Japan the advanced students did the same thing; they had their winter courses at the college, and the summer was spent in the large Government workshops; the system worked very well indeed.[1] In Germany recently the great unions of manufacturers made facilities for giving a year of real factory work to the polytechnic students, but it seems to me that these men are much too old for entrance to works, and, besides, a year is too short a time if the finished product is to call itself a real engineer. Possibly the British solution may be quite different from any of these. A boy may enter works at fourteen on leaving a primary school or not later than sixteen on leaving a secondary school. In either case he must have the three powers to which I have already referred so often. It will be recognised as the duty of the owners of works to provide, either in one large works or near several works, in a well-equipped school following the Finsbury principle, all the training in the principles underlying the trade or profession which is necessary for the engineer.

No right-thinking engineer has been scared by the newspaper writers who tell us of our loss of supremacy in manufacture, but I think that every engineer sees the necessity for reform in many of our ways, and especially in this of education. People talk of the good done to our workmen's ideas by the strike of two years ago; it is to be hoped that the employers' ideas were also expanded by their having been forced to travel and to see that their shops were quite out of date.[2] In fact, we have all got to see that there is far too much unskilled labour among workmen and foremen and managers, and especially among owners. There may be some kinds of manufacture so standardised that everything goes like a wound-up clock and no thought is needed anywhere; but certainly it is not in any branch of engineering. Many engineering things may be standardised, but not the engineer himself. Millions of money may build up trusts, but they will be wasted if the unskilled labour of mere clerks is expected to take the place of the thoughtful skilled labour of owners and managers. I go further, and say that no perfection in labour saving tools will enable you to do without the skilled, educated, thoughtful, honest, faithful workman with brains. I laugh at the idea that any country has better workmen than ours, and I consider education of our workmen [3] to be the corner-stone of prosperity in all engineering manufacture. It is from the workman in countless ways that all hints leading to great inventions come. New countries like America and Germany have their chance just now; they are starting, without having to "scrap" any old machinery or old ideas, with the latest machinery and the latest ideas. For them also the time will come when their machines will be getting out-of-date and the cost of "scrapping" will loom large in their eyes. In the meantime they have taught us lessons, and this greatest of all lessons—that unless we look ahead with much judgment, unless we take reasonable precautions, unless we pay some regard to the fact that the cleverest people in several nations are hungry for our trade and jealous of our supremacy, we may for a time lose a little of that supremacy. In the last

[1] The following is, I understand, a stock question at certain gymnasien: "Write out all the trigonometrical formulæ you know." I asked my young informant, "Well, how many did you write?" "Sixty-two," was the answer. This young man informed me that a boy could not pass this examination unless he knew "*all* algebra and *all* trigonometry and *all* science." Strassburg geese used to be fed in France; now they are fed in Germany. German education seems to be like smothering a fire with too much fuel or wet slack which has the appearance of fuel.

[2] I have pointed out how natural it is that business men should feel somewhat antagonistic to college training. Poorly paid, unpractical teachers, with no ideas of their own, have in the past taught in the very stupidest way. They have called themselves "scientific" and "theoretical" till these words stink in the nostrils of an engineer. When I was an apprentice, and no doubt it is much the same now, if an apprentice was a poor workman with his hands he often took to some kind of study which he called the science of his trade. And in this way a pawkiness for science got to be the sign of a bad workman. But if workmen were so taught at school that they all really knew a little physical science, it would no longer be laughed at. When a civil or electrical engineer is unsuccessful because he has no business habits, he takes to calculation and the reading of so-called scientific books, because it is very easy to get up a reputation for science. The man is a bad engineer in spite of his science, but people get to think that he is an unpractical man because of his scientific knowledge. I do believe that the unbelief in technical education so very general has this kind of illogical foundation. Four hundred years ago, if a layman could read or write he was probably a useless person who, because he could not do well otherwise, took to learning. What a man learnt was clumsily learnt; usually he learnt little with great labour and made no use of it; therefore reading and writing seemed useless. Now that everybody is compelled to read and write, it is not a usual thing to say that it hurts a man to have these powers.

[1] It was the idea of Principal Henry Dyer.

[2] Not only is there an enormous improvement in the use of limit gauges and checking and tools, and the careful calculation of rates of doing work by various tools and general shop arrangement, but attention is being paid to the comfort of workmen. There are basins and towels, and hot and cold water for them to wash in. In the old days it would have been called faddy philanthropy. Now, owners of works who scorn all softness of heart provide perfect water-closets for their men; their workshops are kept at a uniform temperature; the evil effect of a bad draught in producing colds, or a bad light in hurting the eyes, is carefully considered. In some of these works it is actually possible for a workman or a member of his family to get a luxurious hot bath for a penny. Will this really pay? Some clever, hard-headed men of my acquaintance say they already see that it does pay very well indeed.

[3] The old apprenticeship system of training men has broken down, and this is the cause of most of our industrial troubles. An apprenticeship system suited to modern conditions is described fully on pp. 68–88 of "England's Neglect of Science."

twenty-three years I have written a good deal about the harm done to England by the general dislike that there is among all classes for any kind of education. I do not say that this dislike is greater than it used to be in England; I complain that it is about as great. But I have never spoken of the decadence of England. It is only that we have been too confident that those manufactures and that commerce and that skill in engineering, for which Napoleon sneered at us, would remain with us for ever. Many writers have long been pointing out the consequences of neglecting education; prophesying those very losses of trade, that very failure of engineers to keep their houses in order, which now alarms all newspaper writers. Panics are ridiculous, but there is nothing ridiculous in showing that we can take a hint. We have had a very strong hint given us that we cannot for ever go on with absolutely no education in the scientific principles which underlie all engineering. There is another important thing to remember. Should foreigners get the notion that we are decaying, we shall no longer have our industries kept up by an influx of clever Uitlanders, and we are much too much in the habit of forgetting what we owe to foreigners, Fleming and German, Hollander, Huguenot and Hebrew, for the development of our natural resources. Think of how much we sometimes owe to one foreigner like the late Sir William Siemens.

But I am going too far; there is after all not so very much of the foolishness of Ishbosheth among us, and I cannot help but feel hopeful as I think lovingly of what British engineers have done in the past. We who meet here have lived through the pioneering time of mechanical and electrical and various other kinds of engineering. Our days and nights have been delightful because we have had the feeling that we also were helping in the creation of a quite new thing never before known. It may be that our successors will have a better time, will see a more rapid development of some other applications of science. Who knows? In every laboratory of the world men are discovering more and more of Nature's secrets. The laboratory experiment of to-day gives rise to the engineering achievement of to-morrow. But I do say that, however great may be the growth of engineering, there can never be a time in the future history of the world, as there has never before been a time, when men will have more satisfaction in the growth of their profession than engineers have had during the reign of Queen Victoria.

And now I want to call your attention to a new phenomenon. Over and over again has attention been called to the fact that the engineer has created what is called "modern civilisation," has given luxuries of all kinds to the poorest people, has provided engines to do all the slave labour of the world, has given leisure and freedom from drudgery, and chances of refinement and high thought and high emotion to thousands instead of units. But it is doing things more striking still. Probably the most important of all things is that the yoke of superstitions of all kinds on the souls of men should be lifted. The study of natural science is alone able to do this, but education through natural science for the great mass of the people, even for the select few called the distinguished men of the country, has been quite impossible till recently. I say that it is to engineers that the world owes the possibility of this new study becoming general. In our country nearly all discoveries come from below. The leaders of science, the inventors, receive from a thousand obscure sources the germs of their great discoveries and inventions. When every unit of the population is familiar with scientific ideas, our leaders will not only be more numerous, but they will be individually greater. And it is we, and not the schoolmasters, who are familiarising the people with a better knowledge of Nature. When men can hardly take a step without seeing steam-engines and electro-motors and telegraphs and telephones and steamships, with drainage and water works, with railways and electric tramways and motor-cars; when every shop-window is filled with the products of engineering enterprise, it is getting rather difficult for people to have any belief in evil spirits and witchcraft.

All the heart-breaking preaching of enthusiasts in education would produce very little effect upon an old society like that of England if it were not for the engineer. He has produced peace. He is turning the brown desert lands of the earth into green pastures. He is producing that intense competition among nations which compels education. If England has always been the last to begin reform, she has always been the most thorough and steadfast of the nations on any reform when once she has started on it. Education, pedagogy, is a progressive science; and who am I that I should say that the system of education advocated by me is that which will be found best for England? In the school education of the average boy or man England has as yet had practically no experience, for she has given no real thought to it. Yet when she does, I feel that although the Finsbury scheme for engineers may need great improvement, it contains the germ of that system which must be adopted by a race which has always learnt through trial and error, which has been led less by abstract principles or abstract methods of reasoning than any race known in history.

NOTES.

WE learn from the *Times* that the work at the Ben Nevis Observatory is to be continued for another year without change in its character. The Meteorological Council in London has agreed to continue its grant of 250*l.* to the low-level observatory at Fort William and the grant of 100*l.* to the high-level observatory. The proceeds derived from furnishing newspapers with meteorological reports and from other sources will amount, it is hoped, to about 150*l.*, the sum hitherto yielded. The balance of the cost of maintenance, amounting to about 1000*l.*, has been readily subscribed by the public. This satisfactory arrangement will enable the staff to prosecute its work without interruption until the Parliamentary Committee inquiry has reported.

REUTER telegrams state that both craters of the Soufrière have been active since September 11, that communication by wireless telegraphy is to be established between Martinique and Guadaloupe, and that a shock of earthquake was felt in many of the northern towns of South Australia on Friday morning last. A severe shock was also experienced in Adelaide in the evening of the same day.

THE medals and prizes will be distributed to the students of the Royal College of Science, South Kensington, in the theatre of the Victoria and Albert Museum at 2.30 p.m. on Thursday next. The opening address of the new session will be delivered by Prof. John Perry, F.R.S., and Sir Arthur Rücker, F.R.S., will also speak.

THE death is announced in the *Athenaeum* of Theodor v. Heldreich, director of the Botanic Gardens at Athens. The deceased botanist, who was in his eighty-first year, devoted his attention mainly to the flora of Greece, and was the author of numerous works.

AMONG the deaths of foreign men of science we notice the following:—M. Damour—a member of the Paris Academy of Sciences—at the age of 94, and Prof. O. G. Nordenström, of the Stockholm School of Mines. The former was well known for his chemical analyses of rare minerals, and the latter was an authority on mining and the author of numerous technical memoirs.

THE suggestion that a public subscription should be opened for the purpose of purchasing the house in which Pasteur was born and presenting it to the town of Dôle was brought before the French Association at its recent session.

A SCHEME has been proposed to the Italian Minister of Posts and Telegraphs by Mr. Marconi for the creation of a radio-telegraphic station communicating with the stations established or to be established by the Marconi companies in London and in America. The scheme, which is still under consideration, would, if carried out, cost about 70,000 lire. It was announced at a dinner given in Mr. Marconi's honour that the King of Italy had bestowed the Cross of a Grand Officer of the Italian Order of the Crown upon the inventor.

A PRELIMINARY report on the subject of the wireless telegraphy experiments conducted by a board of naval officers

has, according to the *Western Electrician*, been submitted to the U.S. Navy Department. The board reported that it had tried the Rochefort system with some success, messages having been received and sent with accuracy, and that it was now proposed to test in turn a French and two German systems.

ON Friday afternoon last, Mr. Stanley Spencer, the aëronaut, sailed from the Crystal Palace in the airship he has constructed. A successful voyage over London was made, and the vessel descended at Eastcote, near Pinner.

THE *British Medical Journal* states that arrangements are nearly completed for the formation of a new society to be known as the Therapeutical Society, which shall concern itself with the medicinal properties of every kind of natural product of value in practical medicine. As new countries are opened up, plants hitherto unknown are brought to this country, and, as our contemporary remarks, the society may fulfil a most useful function if it undertakes to study the chemical, pharmacological and therapeutical qualities of such plants, especially those which are believed by the natives of the countries from which they come to possess valuable medicinal properties. The first president will be Sir W. T. Thiselton-Dyer, K.C.M.G., F.R.S., and the first hon. secretary Dr. T. E. B. Brown, master of the Society of Apothecaries. The meetings are to be held in the house of the Society of Apothecaries, and the first will take place shortly to make the necessary preliminary arrangements for the first year's work.

PART of an expedition for the survey of the Gold Coast set sail from Liverpool on Saturday last. The remaining members of the expedition, numbering between thirty and forty, and consisting of trained surveyors from the Ordnance Survey and surveyors from Queensland and New Zealand, will leave for West Africa on October 4.

AN inquiry into the earthquakes in Guatemala and Martinique has been undertaken by Prof. Sapper, of Tübingen, who has obtained leave of absence for the purpose from the Württemberg Government.

AN international exhibition of photography is to be held in Moscow in the spring of next year. It will be divided into the following sections:—(1) Scientific photography; (2) artistic photography; (3) photography applied to printing; (4) works on photography; (5) technical applications of photography; (6) photography considered as a special industry.

THE following rewards are offered by the Government of South Australia for the discovery and working within the State of a deposit or deposits of marketable mineral manure—500*l.* if found on Crown lands; 250*l.* if found on freehold lands. It is stipulated (1) that the deposit is easily accessible and within a reasonable distance of a railway or seaport, and not within twenty-five miles of any discovery on account of which any bonus has been paid; (2) that the deposit is sufficiently abundant and is available at a price which will allow of it being remuneratively used for agricultural purposes; (3) that the product is of a good marketable quality, averaging not less than 40 per cent. of phosphate of lime. In the event of a phosphate of a lower average composition being discovered, it may be recommended that a portion of the reward be paid. Applications must reach the Minister for Agriculture, Adelaide, not later than December 31.

IT was found from the examination of 55,000 children in some thirty-six public schools in New York that no fewer than 12 per cent. suffered from contagious diseases of the eyes. To prevent such children from attending the institutions, a routine examination of the eyes is in future to be made at regular intervals, and for this purpose ophthalmic surgeons have been appointed.

JUDGING from the reports issued by the teachers in the various West Indian islands, the experiment of introducing the subject of agriculture into the elementary schools, which was due to a suggestion made by the Commissioner of the Imperial Department of Agriculture, has already begun to yield satisfactory results. The best accounts come from Jamaica, where the training college at Kingston provides a suitable centre for imparting instruction to teachers in training and special classes; here, too, good practical work has been accomplished. School gardens are being instituted, notably in Jamaica, Trinidad and Tobago, but in some of the islands they have not proved so successful owing to predial larceny. A full account of the agricultural conference appears in the last number of the *West Indian Bulletin*, when besides these reports several papers of an economic nature were read. The Hon. Sydney Olivier pointed out the necessity for careful sorting and good packing of exported fruit if West Indian growers hoped to establish a market in England and America. He suggested that an inspector should be appointed to report on the condition of the fruit as it arrived at its destination. The Hon. W. Fawcett read a paper on the banana industry in Jamaica, which gave general information on the habits of the plant and its method of cultivation. Statistics show that at present the exports to England are small in proportion to those shipped to America. Mr. A. Howard brought forward evidence to show that epiphytes do harm to cacao trees mainly by blocking up the lenticels. He advised spraying with copper sulphate or rosin compound to kill off the smaller plants. Other papers were, "Insect Pests," by Mr. H. Maxwell-Lefroy; "Barbados Aloes," by Mr. W. G. Freeman; and "Essential Oils," by Mr. J. H. Hart.

THE issue of the *Elektrochemische Zeitschrift* for August contains a useful reference article by Dr. H. Lienau on bauxite. This mineral is the chief source of the commercial aluminium produced by the electrolytic processes, and although many attempts have been made, and are still being made, to replace it by some cheaper raw material, these attempts hitherto have been unsuccessful. Natural deposits of bauxite occur in France, Germany, Ireland and the United States, those of the department Var in southern France being at present the most extensively worked. In 1896 this district produced 29,620 tons and in 1901 65,000 tons, of which total 55,000 tons were exported to other countries. After a reference to the geological formation in which bauxite occurs and to the varying composition of the deposits, the author describes the various processes which have been worked at one time or another for extracting aluminium or its compounds from this source. The first patented process dates from 1858, and had for its object the extraction of aluminium hydrate from red bauxite. The demand by paper and colour manufacturers for a cheaper source of aluminium sulphate than the alums turned attention to the direct production of aluminium sulphate from bauxite, but the efforts to produce this salt, free from iron, from red bauxite have not been completely successful. The utilisation of bauxite for the electrometallurgical production of aluminium is a comparatively recent development, but very large quantities of the mineral are now being used in aluminium reduction works. The author surmises from this fact that bauxite is being employed directly in the electrolytic baths, and that the troublesome and costly process by which alumina was first extracted from the raw bauxite is now being dispensed with.

Mr. F. Krohn sends from Funchal, Madeira, some notes on sunset glows observed by him during June, July and August, in continuation of those previously described by him (p. 199). On a number of occasions, even when the sky above and to the west was overcast at sunset, a pink glow could be seen on the eastern horizon just before sunset, and then just immediately after or at the time of sunset a pink glow would suffuse the cloud screen above. Mr. Krohn was under the impression that the phenomenon was rather more marked about July 6–7, 12–16 and 26–27, but these dates, especially the last two, are uncertain. Since the end of July, clear weather has prevailed, and during August 1–3 a well-marked maximum was observable, the phenomenon being particularly well marked on August 2, when both sunrise and sunset displays were very fine, the sky at the time being quite clear. The latter sunsets, however, were very far from equalling the displays of June 10–11. The rays or spokes in the pink haze, mentioned in Prof. A. S. Herschel's letter of July 10 (Nature of July 24), have been observed by Mr. Krohn four or five times. From the observations it is concluded that the volcanic dust and moisture cloud is travelling at an average rate of about thirty miles an hour in the latitude of Funchal. This does not seem an improbable rate if Prof. Herschel's estimate of the height of the present cloud is correct, for the rate at which the Krakatoa cloud travelled was about seventy-two miles an hour; but this cloud was travelling at a much greater height.

When well marked, the phenomena observed by Mr. Krohn at sunset followed the course described by Prof. Herschel. In Mr. Krohn's words, "A pink glow appears in the east in the form of a broad band above a broad greenish-grey band down on the horizon. The pink band gradually extends upwards and disappears as the glow begins to form a pink arc in the western horizon, which until then shows a white hazy area above the sun's point of setting. Gradually the white area contracts and assumes a more golden hue. The pink arc also contracts and assumes a more intense colour; at the outer edge it is more purple where the pink mixes with the blue of the sky. A dirty greenish-grey haze now begins to spread upwards from the eastern horizon and finally replaces the pink halo in the west as a purplish-grey arc around a whitish halo. This faint purplish halo or arc is visible for some time after dusk has set in. At sunrise the phenomena are practically the same, but the order is reversed and the colours near the horizon seem to be purer."

The director of the Philippine Weather Bureau, the Rev. Fr. José Algué, S.J., has issued the first part of a report containing an account of the climate of Baguio (Benguet), as gathered from a complete year's observations. The report is very thoroughly made and is the first of its kind, and one of its main objects is to draw attention to climatological conditions of certain regions of the archipelago which might be advantageously chosen as health resorts. In the case of each of the meteorological elements here discussed, a comparison of the facts is made with the data already recorded at and published by the Manila Observatory. The meteorological station at Baguio is of quite recent date, having been in operation since August, 1900, and its equipment was made more complete after the establishment of the Philippine Weather Bureau in May, 1901. The present report contains the observations of pressure, temperature, relative humidity, fog, clouds, rainfall, wind, and in most cases curves of the daily and yearly variations are given. The concluding chapter is devoted to a comparison of the climate of this station with those of other tropical stations at similar altitudes.

The trustees of the British Museum at Bloomsbury have issued a capital "Guide to the Antiquities of the Stone Age in the Department of British and Mediæval Antiquities," which is accompanied by ten plates and 142 other illustrations. It has been prepared by Mr. Charles H. Read, who observes that his work is to some extent rendered incomplete owing to the fact that many objects essential to a full understanding of the Stone age are at the Natural History Branch in Cromwell Road, while some localities and some classes of implements are not so well represented as they should be in the national collection. Although he groups the antiquities under those of Palæolithic and Neolithic ages, he figures and describes certain Eolithic implements, recognising that the existence of an earlier and ruder type is in itself not improbable. His reference to the occurrence of "early Palæolithic" implements in beds older than the chalky boulder clay, though based on a statement in a Geological Survey memoir, requires qualification, as the evidence is far from satisfactory. The text is, however, so full of information and the illustrations are so excellent, exhibiting the chipped and polished stone-implements from all parts of the world, as well as engraved stones, bones and horns, and pile-dwellings, that the work will be highly appreciated by all who take an interest in the antiquity of man.

Mr. T. Mellard Reade has given an account of the Glacial and post-Glacial features of the River Lune and its estuary (*Proc.* Liverpool Geol. Soc., vol. ix 1902). The lower part of the valley is a pre-Glacial excavation that was filled with Boulder-clay and other glacial drift, and since to a large extent removed by river denudation, the various stages being recorded by terraces cut in the drift. The later deposits include thick sands and clayey sands rich in foraminifera, of which lists have been furnished by Mr. Joseph Wright.

A full account of a recent peat and forest bed at Westbury-on-Severn has been contributed by Mr. Mellard Reade, Mr. A. S. Kennard and others to the *Proceedings* of the Cotteswold Naturalists' Field Club (vol. xiv. part 1). The deposits include blue clays containing foraminifera, an intermediate peat bed with branches and roots of trees, and an overlying mass of tidal alluvium. The foraminifera appear to have lived in the locality and probably in brackish water. The peat bed has yielded many land and fresh-water mollusca, which with other remains indicate climatic conditions similar to those of the present day. The deposits are recent, and the indications they furnish of changes of level prior to the Roman occupation are briefly discussed.

A paper by E. Guyou, entitled "La Méthode des Distances Lunaires, le Présent, le Passé, l'Avenir," has reached us. The author considers that the publication of lunar distances of certain stars in the national ephemerides has had a bad effect in that it has concentrated observation upon those stars all of which at the moment of observation are possibly too far from the moon for accurate observation, and that therefore repeated failure to obtain accurate results has led to the abandonment of the method. The author expects now to see the method revive, observers being no longer biassed in their choice and taking the most convenient star. We think he is too sanguine.

The chemical composition of tubercle bacilli derived from various sources, especially in regard to the amount of ash and of phosphoric anhydride, and of the alcoholic, ether and chloroform extracts, has been investigated by De Schweinitz and Dorset. There is a distinct difference in the composition of the various bacilli; the alcoholic extract of avian bacilli is very much greater than that of any other variety, but the chloroform extract of bovine and of human virulent bacilli is almost the same. There is also a greater difference between the virulent and non-virulent human bacilli than between the virulent human, bovine and equine bacilli. (*Amer. Med.*, July 19, p. 93.)

IN the August number of the *American Chemical Journal* is an interesting paper by Messrs. Franklin and Stafford on reactions between acid and basic amides in liquid ammonia. Solutions of these amides in liquid ammonia are conductors of electricity, a fact presumably due to electrolytic dissociation of the dissolved substances. It would appear that these amides indeed bear a relation to liquid ammonia which in many respects is very similar to that borne by ordinary acids and bases to water. Complete or partial neutralisation of the dissolved amides takes place with the formation of one or more molecules of the solvent ammonia in which the reaction takes place. By bringing together liquid ammonia solutions of different acid and basic amides, the authors have prepared a large number of metallo-substituted acid amides; for example, monopotassium acetamide, mono- and di-potassium benzamide, mono- and di-potassium sulphamide, mono- and di-potassium urea, magnesium acetamide, &c.

IN a *Bulletin* of the Bussey Institution, vol. iii. No. 2, Prof. F. H. Storer describes the results of tests for mannose carried out on a large number of vegetable species. From these it would appear that mannan is fairly widely distributed in plant life. The amount of mannan in the trunk-wood of sugar-maple trees felled during the period of hibernation is considerably greater than that in maple trees felled at the beginning or end of May, that is, during or just after the formation of new leaves upon the trees. The author comes to the conclusion that mannan as well as starch is stored as reserve food in the wood of the sugar maple.

THE sixteenth number of the *Revue générale des Sciences*, issued on August 30, contains a short article, by Mr. P. Lemoult, on the new synthesis of indigo patented by Sandmeyer. The author points out that the Sandmeyer synthesis possesses several advantages, from a chemical point of view, over the two processes which are now used on the large scale for the artificial production of indigo. An estimate of the cost of production by the new process indicates that the indigo obtained should compete successfully on the market with the natural product and that of the older synthetic methods.

IN vol. xvii. of the *Journal* of the College of Science, Imperial University, Tokyo, Messrs. Divers and Ogawa show that it is possible to prepare sulphamide from ammonium amidosulphite with a 10 per cent. yield, whereas the older method of obtaining it from sulphuryl chloride and ammonia only gives 1 to 2 per cent. of the theoretical amount.

To the September number of the *Zoologist*, Mr. R. C. J. Swinhoe contributes some important notes on prehistoric man in Burma. It will be remembered that in 1894 Dr. F. Noetling announced in the *Records* of the Geological Survey of India the discovery in a bed of ferruginous conglomerate at the oil-fields of Yenangyoung of worked flints in association with the remains of *Hipparion antilopinus* and *Rhinoceros perimensis*, thus carrying back the existence of man in that country to the older Pliocene or upper Miocene. A year later, Mr. R. D. Oldham expressed the opinion that, in the first place, the flints are not confined to the ferruginous conglomerate and, secondly, that they are not chipped by man. As the result of a recent visit to the locality, Mr. Swinhoe confirms Dr. Noetling's view that the chipped flints, and likewise certain facetted bones, are the works of men's hands; but, on the other hand, he regards them as of Palæolithic age, the place where they were found being apparently a workshop of that period.

THE September issue of the *Quarterly Journal of Microscopical Science* contains four articles of a highly technical nature, for the most part interesting only to specialists. In the first of the four, Dr. T. H. Bryce treats of the maturation of the egg in the common sea-urchin; he is followed by Mr. R. I. Pocock, who discusses the "entosternite" of spiders and scorpions. The third article, by Dr. S. F. Harmer, is devoted to the morphology of polyps allied to the common sea-mat, while in the fourth, Mr. L. Doncaster describes the development and anatomy of the annelid sagitta.

NOS. 1275 and 1276 of the *Proceedings* of the U.S. Museum are respectively devoted to a list of the beetles of the Columbia district, by Mr. H. Ulke, and to the description of some new South American birds, by Mr. H. C. Oberholser.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mrs. O'Connor; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss Faulkner; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. C. W. Woodhouse; a Black-headed Lemur (*Lemur brunneus*) from Madagascar, presented by Dr. H. C Hilliard; a Grey Parrot (*Psittacus erithacus*) from West Africa, presented by Captain Paget J. Bourke; a Carrion Crow (*Corvus corone*) British, presented by Miss N. Simmons; a Great Barbet (*Megaloema virens*) from the Himalayas, presented by Mr. R. Phillips; eighteen Green Tree Frogs (*Hyla arborea*) European, presented by Dr. E. L. Gough; a Common Marmoset (*Hapale jacchus*), an All-green Tanager (*Chlorophonia viridis*), a Blue Sugar-bird (*Dacnis cayana*) from Brazil, a Suricate (*Suricata tetradactyla*) from South Africa, a Prairie Marmot (*Cynomys ludovicianus*) from North America, a Crab-eating Opossum (*Didelphys cancrivorus*) from Tropical America, a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, three Asiatic Quails (*Perdicula asiatica*) from India, deposited; an Axis Deer (*Cervus axis*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER:—

Oct. 10. 0h. 41m. to 5h. 34m. Transit of Jupiter's Sat. IV.
12. 2h. 7m. to 5h. 49m. Transit of Jupiter's Sat. III.
13. 11h. 24m. Minimum of Algol (β Persei).
15. Venus. Illuminated portion of disc = 0·981, of Mars = 0·930.
16. 8h. 13m. Minimum of Algol (β Persei).
16. 10h. 17m. to 11h. 18m. Moon occults ζ^1 Piscium (mag. 4·2).
16. 16h. 17m. to 19h. 50m. Total eclipse of the moon partly visible at Greenwich. The moon sets at 18h. 32m. when totally eclipsed.
19. 5h. 58m. to 9h. 40m. Transit of Jupiter's Sat. III.
19. 17h. 8m. to 18h. 13m. Moon occults δ^1 Tauri (mag. 4·0).
19. 17h. 43m. to 18h. 43m. Moon occults δ^2 Tauri (mag. 4·7).
19–21. Epoch of Orionid meteoric shower. Radiant $91° + 15°$.
22. 12h. 53m. to 13h. 44m. Moon occults λ Geminorum (mag. 3·6).
23. 9h. Mercury in conjunction with Venus. Mercury, 1° 20′ S.
26. 9h. 54m. to 13h. 36m. Transit of Jupiter's Sat. III.
30. 6h. Venus in conjunction with moon. Venus, 0° 54′ N.
30. Partial eclipse of the sun slightly visible at Greenwich. The eclipse ends at 19h. 1m., or 8 minutes after sunrise at Greenwich on the morning of Oct. 31.

REPORT OF THE MELBOURNE OBSERVATORY FOR 1901.—New buildings are being added at a cost of 1500*l*., and, with the repairs that have already been done, this will add considerably to the efficiency of the Observatory.

The third Melbourne catalogue for the epoch 1890 has been in the printer's hands since last December. 336 plates have been exposed in connection with the astrographic chart, and of these, 320 have been passed as satisfactory.

6327 stars have been selected from the catalogue plates, and roughly reduced for observation with the Melbourne transit circle, to serve as standard stars for the reduction of the Melbourne regions, and of these 3944 have already been completely observed with the meridian circle three times or more.

There are now 760 meteorological stations in communication with the Observatory, and all the records for the last forty years are, at present, being completely rearranged and classified in convenient forms for easy reference. The terrestrial-magnetism work has been carried on as hitherto, and the special observations in connection with the Antarctic expeditions are being made at the required intervals. In the reduction of the magnetograph curves for the past thirty years, 21,877 curves had been measured up to March 31.

NEW MINOR PLANETS.—The following five minor planets, with their positions, are recorded by Prof. Max Wolf in No. 3815 of the *Astronomische Nachrichten* :—

	1902. Sept. 3d. 12h. 55m. ·8 (Heid).		Sept. 7d. 10h. 38m. ·9 (Heid).		
	α	δ	α	δ	Mag.
1902 J.O.	23h. 54m. ·7	$-0^\circ 13'$	23h. 51m. ·7	$-0^\circ 44'$	13
1902 J.P.	23h. 56m. 7	$+1^\circ 14'$	23h. 54m. ·5	$+0^\circ 47'$	12
1902 J.Q.	0h. 13m. ·4	$+1^\circ 20'$	0h. 11m. ·3	$+0^\circ 44'$	12·5
1902 J.R.	0h. 9m. ·2	$-1^\circ 21'$	0h. 6m. ·6	$-1^\circ 36'$	12
1902 J.S.			0h. 10m. ·3	$-0^\circ 13'$	13

THE RETURN OF THE ARCTIC EXPEDITIONS.

SINCE we went to press with our last issue, the Arctic expeditions of Lieut. Peary and Captain Sverdrup have returned, and accounts of their work, as well as of that of the Baldwin-Ziegler expedition, have appeared in the daily papers. The following brief account of the scientific results obtained by the three expeditions is obtained from telegrams received through Reuter's Agency, and from the personal narrative of Captain Sverdrup which is to be found in the *Times* of Monday last.

Lieut. Peary reached Payer Harbour on September 16, 1901, and within a week the Eskimos with the expedition began to sicken, and not one escaped illness. Of the number, six adults and a child died. Further sickness among the Eskimos occurred in the following January.

An advance party, in charge of Hensen, started for Conger on March 3. On March 6, the main party started, leaving Peary in charge at Payer Harbour. Conger was reached in twelve marches, shortly after the advance party had arrived there. The Eskimos supporting the expedition went back on reaching Conger. Eight marches more took the expedition to Cape Hecla, at the north end of Robinson Channel, which was all open across to Greenland, while there were lakes of water extending northward as far as could be seen, from Black Cape to Cape Ransome. On April 1, Lieut. Peary started northward over the Polar Sea with Hensen, four Eskimos and six sledges. The old floes were covered deeply with snow and intersected by rubble ridges, and lanes of young ice were encountered.

The travelling, except for the lanes of young ice, was similar in character to that experienced by the English expedition of 1876. After a number of difficult marches, which became more and more perilous, the pack, in latitude 84° 17′, to the north-west of Cape Hecla, became impracticable, and further efforts to advance had to be abandoned. New leads and the pressure ridges, with fogs, made the return in some respects more trying than the advance. Cape Hecla was regained on April 29 and Cape Sabine on May 15. The ice broke up earlier than in 1901, and Payer Harbour was blockaded almost continuously. The *Windward* bored through, entered the harbour on August 8, and left the same afternoon.

The leader of the expedition states that he has a deep-rooted conviction that it is possible to reach the North Pole. In all his attempts during the last four years, he points out, he has not had a suitable starting-point, but he believed that the Pole can be reached on sledges by any adequately equipped expedition which makes latitude 83 its winter quarters. If he had means of his own to continue the work, he would certainly not give it up, but he must now bow to circumstances. It has been demonstrated to his satisfaction, he declares, that there is no open ocean in the voyage to the Far North. On the other hand, there is no foundation for the idea that there is an eternally frozen sea, though the waters are practically always covered with ice. He has shown, he thinks, that Greenland's shore is the most northerly land of the earth's surface, and that all beyond it on the other side is ocean.

Lieut. Peary made a close study of the Eskimos living on Whale Sound, the most northerly people in the world. Their complete isolation has differentiated them from every other race. They are a small tribe, not exceeding 200 in number, and are being rapidly destroyed by an unknown disease, apparently a malignant slow fever. He collected specimens of everything pertaining to their habits, knew every man, woman and child personally, learned their characters and capacities, and taught them to work.

The first intimation of the return of Capt. Sverdrup in the *Fram* came in the shape of the following telegram (dated Stavanger, September 19) from Captain Sverdrup to the secretary of the Royal Geographical Society :—

"Arrived here to-day with the *Fram*. Our exploring work consists in the southern and the western shores of Ellesmere Land and other unknown fields to the westward. Braskerud died autumn 1899, otherwise all well."

The *Fram*, it will be remembered, left Christiania in June, 1898, its principal geographical object being to ascertain the extension of Greenland towards the north, to determine the yet unknown configuration of the mainland, and, if possible, to discover whether this great Arctic land finally breaks up into groups of islands in the north. It was also understood that, if circumstances were favourable, Captain Sverdrup, like Lieut. Peary, would make an attempt to reach the North Pole.

The personal narrative of the leader of the expedition, already referred to, gives an interesting account of the work accomplished and the way in which the great difficulties which presented themselves were overcome. As so much care and attention had been paid to the scientific equipment of the expedition, valuable scientific results may be expected to accrue from it, particulars of which will be eagerly awaited. The narrative, however, gives information as to some of the work done in the interests of science. Hayes Sound was completely mapped. The unknown west coast of Ellesmere Land was explored. Between Ellesmere and North Kent, a large bay was seen to extend eastward and to be about 100 miles broad. On the northern side of the same, some large, complicated fjords were found. The land extended about fifty miles westward from these, after which it ran in a north and north-westerly direction. Part of the land which was traversed was very hilly and intersected by large fjords, several of which were from fifteen to twenty miles broad at the mouth.

Much other new land was explored and the numerous fjords investigated. All the members of the expedition appear to have worked heartily and harmoniously together, and returned safely to Stavanger on Friday last, with the exception of the surgeon, who was to have taken charge of the meteorological observations and who died in the course of the expedition.

Mr. Baldwin, in the course of an interview, claimed to have accomplished, in the course of nearly a year and a half's incessant work, more than the unfavourable conditions which surrounded his expedition really warranted, and to have brought back data which ought materially to assist subsequent explorers. For the first time in the history of North Polar exploration, a photographic record had been secured of the ice and snow conditions of the Arctic and of the animal life of those regions. The kinematograph had been for the first time successfully employed in the far North, and as a result there were more than 1000 perfect photographic representations of their work, and in addition more than 200 drawings and paintings had been made.

The main object of the expedition was to plant the American flag at the North Pole, and the result being what it was, the explorer is naturally somewhat disappointed. He maintains, however, his belief that his objective can be reached in accordance with his original plan. He attributes his non-success to the condition of the ice in the Franz Josef Land Archipelago in the autumn of 1901, which prevented the navigation of the *America* far enough north to be of practical advantage in establishing headquarters so as to facilitate sledge-work in the winter and spring of the present year, and to the sickening and death of many of the dogs from internal parasites, which ultimately proved fatal to more than half the pack.

A hut was found by the party, and in it a small brass cylinder

3 inches in length containing a record of Dr. Nansen's work, dated May 19, 1896, the hut proving to be that in which Nansen had stayed. In the place of the document, Mr. Baldwin left a record by himself of his own work and visit.

During the period spent by the expedition in the far north, some fifteen balloons were released containing messages, addressed to the nearest American Consul, respecting both air and sea currents.

After an adventurous and trying journey, the expedition, on July 17, reached a place of safety to the southward of Cape Flora, and eventually home. In Mr. Baldwin's opinion, the old idea of an open Polar sea is baseless. "We know," he says, "that land extends as far as the 82nd degree on the Franz Josef Land side, and it is from here that I believe the Pole will be reached. I quite agree with Lieutenant Peary that the most practical way of attaining the Pole is by sledging from this point."

CONVENTION OF WEATHER BUREAU OFFICIALS.

ON August 27, 28 and 29 of last year, the second Convention of Weather Bureau Officials took place at Milwaukee, Wisconsin, and we have recently received the report of the proceedings, which has been published by the U.S. Department of Agriculture (*Bulletin* No. 31), being edited by Messrs. James Berry and W. F. R. Phillips under the direction of the chief of the Weather Bureau, Prof. Willis L. Moore. The report, which covers no less than 246 pages, will be found most interesting reading to meteorologists, for the numerous papers included in the seven sections of the volume refer to widely varied branches of work. To enter into anything like detail in this note is out of the question, but brief references may be made to a few of the papers read at this Convention.

Prof. Moore in his presidential address gave a brief survey of the weather service since its inception in 1870, showing its rapid growth and pointing out its increasing efficiency. "Fog Studies" was the subject of Prof. Alex. McAdie's paper, the author emphasising the point that fog "may be considered as a problem in *air drainage*, just as frost may be so considered." We reproduce one of the numerous excellent reproductions in the report with which he illustrated his remarks. Mr. E. J. Glass describes and illustrates the "chinook" winds so well known to those who live near the Rocky Mountains and which serve the useful purpose of storing the snow that supplies the water to the rivers during the summer season.

FIG. 1.—Fog Pyramid. This photograph was taken by Prof. Alex. McAdie on July 30, 1900, at 7.15 p.m. The conditions were normal so far as temperature, humidity and wind are concerned at Mount Tamalpais. The view in the foreground is the town of Mill Valley. The apex of the fog pyramid was (it is estimated) about five miles from the camera. The fog in the background overlies the Golden Gate and the Bay of San Francisco. The formation is peculiar, and it should be noted that the land under the fog pyramid is level, and the uplifting of the fog is not due to the existence of foothills at this point.

Amongst other papers of particular interest are those referring to "the forecaster and the newspaper," by Mr. Harvey Maitland Watts, who points out the great value newspapers can be in publishing popular and accurate meteorological information and timely warnings to their readers. Dr. Oliver Fassig gives the results of a study of the diurnal variations of the barometer, and demonstrates the westward movement of the daily barometric wave, portraying it excellently by means of a series of charts which accompany the paper. In the subsequent discussion, Prof. Moore refers to the paper as "quite unique and entitled to great consideration." "Lightning Recorders and their Utility in Forecasting Thunderstorms," "Meteorology in Colleges," &c., are among other subjects touched upon, and the volume concludes with a good index and a capital photograph of a group of the members present at this Convention. There seems no doubt that such gatherings are most useful and valuable, and Prof. Moore tells us that these two conventions have demonstrated their usefulness by affording exceptional opportunity for exchange of views and discussion of methods and means for advancing the work of the Weather Bureau.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE technical schools and colleges throughout London are now beginning their winter's work. An examination of a batch of prospectuses which has reached us shows that year by year there is an increasing amount of attention paid to the varied wants of students engaged throughout the day in different industries. At the Battersea Polytechnic, for example, we notice that in addition to the lectures and laboratory work in inorganic, organic and physical chemistry, classes have been arranged in gas manufacture, in the manufacture of oils, fats, soaps and candles, in iron and steel analysis, in paper making and testing, and in the chemistry of the kitchen and laundry. The same thoroughness is shown in the departments concerned with the building, engineering and other trades. The prospectus of the Chelsea Polytechnic, over which Prof. Tomlinson, F.R.S., presides, is published in four volumes dealing respectively with the day colleges for men and women, the day school for boys and girls, and the evening classes. It would be difficult to name a subject, commercial or technical, in which no class is provided at Chelsea. Moreover, every stage is looked after; there are classes suitable for the apprentice, and yet arrangements have been made by which advanced students may engage in research work under the supervision of the principal.

The Sir John Cass Technical Institute at Aldgate is just entering upon its first full session. Intending students will find that complete chemical, metallurgical and physical courses of instruction have been provided, as well as classes in commercial and domestic subjects. Considerable attention appears to have been given to the preparation of candidates for examinations in connection with the University of London.

THE Report for the year 1901 on the museums, colleges and institutions under the administration of the Board of Education has been issued. Among other interesting items, it may be mentioned that the year was marked by a large falling off in the number of visitors to the western galleries of the Victoria and Albert Museum who received special assistance or facilities for the examination of the collections for scientific instruction and research. There was also a diminution in the total number of visitors to the Museum, the total in 1901 being 836,848 as compared with 1,017,314 in 1897, since which year there has been a steady decrease. The most important events in the history of the Royal College of Science during the year reported upon were the retirement of Sir Norman Lockyer after forty-four years' total service, and of Sir Arthur Rücker after fifteen years' service. Similarly the report of the Geological Survey is exceptional, since it records the retirement of Sir Archibald Geikie after a service of more than forty-five years. The Solar Physics Observatory was very busy during the fifteen months with which its report deals, viz. from October, 1900, to December, 1901. Bad weather entirely prevented observations of sun spots on 127 days throughout this period, and 171 nights during the same time were wholly bad for observing purposes, leaving 201 nights available, on which occasions the observers attended.

THE Report of the Board of Education for the year 1901–2 contains much interesting information concerning the amount and quality of the science teaching in schools working under the regulations of the South Kensington authorities. During the session 1900–1, the total number of students receiving instruction in science and art in such schools was 332,329, and the total number of such schools or institutions was 2288. The grants paid in respect of the instruction given, or of the examinations held at its close, amounted to 286,251*l.*, of which it is interesting to note 2687*l.* only was paid on the results of the annual examinations, by far the greater part being awarded upon attendances or in the form of capitation grants in "schools of science." The new regulations, under which fees became payable by candidates for examination in the elementary stage of science subjects, appear to have had a beneficial effect. The percentage of these papers which reached the first class rose from 27 in 1900 to 31 in 1901 under the new regulations, and of those which reached the second class from 32 to 37, the percentage of failures thus falling from 41 to 32. Up to the end of 1901, 78 schools in England and 65 in Wales applied for recognition under the new regulations, which offer grants to secondary day schools taking an approved scheme of instruction for a three or four years' course in science. Of the English schools, 58 were endowed schools, 6 were county or municipal schools, 9 were established by articles of association and 5 by religious bodies. As these regulations only came into force in August, 1901, none of the schools had, at the time of drawing up the report, completed the first year's course, so that no account of the way in which the new arrangements work is yet available.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 15.—M. Bouquet de la Grye in the chair.—The cultivation of the yellow lupin (*Lupinus luteus*), by MM. P. P. Dehérain and E. Demoussy. The poor yield of this plant on calcareous soil appears to be due to the effect of the lime in preventing the assimilation of phosphoric acid, since if considerable quantities of phosphate are added, the plant will grow in soils containing a fair proportion of lime. The tubercles containing bacteria capable of fixing atmospheric nitrogen do not, however, appear under these conditions, not even when the yellow lupins are inoculated from the tubercles of white lupins. The growth is best in non-calcareous soils.—On the principal focal surface of the objective of the photographic equatorial of the Observatory of Toulouse, by MM. B. Baillaud and Montangerand.—On the rocks thrown out by the actual eruption of Mont Pelée, by M. A. Lacroix. From the external appearances, three classes of rocks can be distinguished, compact vitreous blocks of a greyish-black colour, rocks of a clearer colour than these, and angular blocks of white pumice, sometimes as large as a cubic metre. All these have proved to be of the same petrographical type; they consist of hypersthene andesites rich in phenocrystals, the latter consisting of plagioclases of the andesine and bytownite series. The principal coloured element is hypersthene, accompanied by titanomagnetite and small quantities of augite, hornblende and olivine. The products of the eruption have the same general character as the rock mass of Mont Pelée formed in the course of previous eruptions.—On the differences of contact potential, by M. Pierre Boley. A study of the electromotive forces of the cell constructed of the saturated amalgams of two metals, with two electrolytes.—On the electrical resistance of slightly conducting bodies at very low temperatures, by M. Edmond van Aubel. The electrical resistance of iron pyrites was measured for a temperature range of from 60° C. to −181° C. The resistance increases considerably as the temperature is lowered, but there is still an appreciable conductivity at the temperature of liquid air. The curve showing the variation of the electrical resistance of iron pyrites with temperature shows that $\frac{\Delta R}{\Delta t}$ increases as the temperature approaches the absolute zero. Experiments on other metallic sulphides are being carried out.—On a note of M. Th. Tommasina, on the mode of formation of kathode and Röntgen rays, by M. Jules Semenov.—On the formation of liquid drops and the laws of Tate, by MM. Ph. A. Guye and F. Louis Perrot. With other conditions fixed, the weight of a drop falling from the end of a tube is a function of the time of formation of the drop. It follows that any attempt to verify Tate's law, in which the time of formation is not taken into account, is wanting in precision. It is essential that the conditions of experiment should be so arranged that the weight of the drop should be independent of the time of formation. In view of these facts, the authors consider that the experiments of MM. Leduc and Sacerdote do not furnish even an approximate proof of the law in question.—On the production of india-rubber in the forests of the French Congo, by M. Aug. Chevalier. Observations on *Landolphia Klainii*, the chief india-rubber-producing tree in the French Congo.

CONTENTS.

THURSDAY, OCTOBER 2, 1902.

FUSILS DE CHASSE.

Tir des Fusils de Chasse. Par Journée, Lieut.-Colonel du 69^e Régiment d'Infanterie. Deux: Edition. Pp. ii + 387. (Paris: Gauthier-Villars et Fils, 1902.) Price fr. 12.

THIS volume on guns, rifles and explosives is divided into eight chapters. The first is devoted to general information about guns and ammunition; for example, the writer states that the *calibre* which we call 16 signifies that sixteen spherical lead balls of the calibre of the gun weigh one pound. The nominal calibres are then shown in a tabulated form reduced to millimetres, also some of the qualities of different powders and shot are described.

In chapter ii. the pressures of powder gases are considered, and a large amount of solid work on this subject has been collected together in section vii. of this chapter. The pressures due to Amberite, Cooppal and Valsrode are shown in a tabulated form.

The action of the gas of explosion was measured by the method of Sébert, by which the successive velocities and accelerations of recoil of a gun are measured during the passage of the shot through the barrel. When the writer comes to the subject of crusher gauges, for determining the pressure of powder gases, he quotes from the *Field*, in which the results obtained by M. Polain, of Liège, were published; the author might have cited with advantage the excellent work on this subject to be found in the *Proceedings* and *Transactions* of the Royal Society of London, vols. lii. and clxv. respectively. In chapter iii. the question of the velocity of the projectile is treated, and the author writes:—

"Mais le plus souvent, on déduit la vitesse initiale de la vitesse restante à une petite distance de la bouche, vitesse qui a été mesurée avec un chronographe électrique, dont le modèle le plus usité est le chronographe de Boulengé."

The Boulengé chronograph, now a rather antiquated instrument, has gained a far-reaching popularity from the fact that nearly anyone can read the results, but the instrument is not at all suitable for determining high velocities over short ranges, and in the case of a shot gun the range for finding the velocity is very short indeed.

The method of dealing with the question by MM. Billardon and Don is far better and exact; it consists of a moving target and a fixed one. The form of this instrument, referred to by the author, has been constructed by Mr. R. Griffith, the manager of the Schultze Powder Co. The moving target consists of a disc 12 feet in diameter, from which a central disc of 4 feet diameter has been removed, leaving a band carried on spokes, 4 feet wide. This is so rotated by a steam engine that the velocity of a point on its edge is 200 feet per second. The edge is marked with divisions, each representing 1/400 sec. From each division lines are drawn to the centre. The band is also ruled with fifteen concentric circles. Thus the whole surface of the band is divided into sections, which can be numbered for reference. In front of the target, and close to it, is a fixed screen covering the lower half of the circular target, except where it is perforated with a circular opening 4 feet in diameter, so placed as to coincide with the width of the band moving behind it. Across this opening a sheet of very thin paper is strained; this receives the stationary pattern of the discharged pellets, while the revolving band receives the pattern made by the pellets striking it in succession. Observations made with the instrument show the relative velocity of the pellets, so that from the observations a diagram may be constructed showing the actual position of the pellets at a given time.

In chapter iv. the recoil of guns is discussed, the velocities of recoil being measured by the method of Sébert; but the instrument employed was far more simple than that of Sébert, and gave results the limit of which is shown by the following quotation from the writer:—"Il permet d'obtenir la vitesse du recul à 1/5000 près." None of the modern methods of working experiments on recoil, such as the pneumatic and electrical methods of firing, are mentioned. Chapter v. is a long one of eighty-one pages, the subject being the dispersion of shot. The author has illuminated this portion of his book with one of the excellent spark photographs of Prof. C. V. Boys, F.R.S., in which the relative position of the pellets is clearly shown. Information on the subject of "choke bore" has been carefully collected, and exhibited in tabular form. The author devotes six pages to the vibration of the gun, and on p. 254 the supposed form of vibration is shown. The excellent and new work of Cranz and Koch on the vibration of gun-barrels does not appear to have been consulted, neither is the method employed in obtaining the results described.

In chapter vi. a large amount of matter respecting the form and nature of bullets has been collected. On p. 269 the name of the celebrated inventor W. E. Metford is wrongly spelt, "d" being written for "t." Alloys used in the manufacture of bullets, both of the heavy and light classes, are described. With respect to the latter, the author writes:—

"Les balles faites en aluminium pur se champignonnent trop facilement sur les os offrant quelque resistance."

Alloys are also mentioned, such as that of aluminium and tungsten, called partinium, and aluminium and magnesium, called magnalium. The latter alloy is becoming popular amongst Continental instrument makers on account of its lightness and tenacity. Bullets made of these alloys would be of great service as man-stoppers at close quarters because of the spread of the bullet.

The chapter concludes with a description of the method of applying the abacus for finding the remaining velocities of projectiles at different ranges, when the initial velocity is given. The abacus now used in calculations connected with technical matters in France is well described in "Le Calcul Simplifié," by Maurice d'Ocagne. By means of the abacus, solutions of many problems may be easily and rapidly found, when the law of the formula employed has been plotted in the form of a graph. The work concludes with a chapter on aiming the gun in sport, and the influence of the nervous condition of the sportsman and the skill of different individuals. The author has collected together a great mass of

 AA

valuable matter on the subject he has taken in hand, and he puts it before the reader with clearness and precision. Should another edition be called for, some of the valuable results obtained by Dr. Bashforth and the more modern work in ballistics, which has been carried on in the United States of America, in Germany and in England, might be introduced with advantage. F. J-S.

THE COMPLETION OF ROSCOE AND SCHORLEMMER'S ORGANIC CHEMISTRY.

Roscoe-Schorlemmer's Lehrbuch der Organischen Chemie. By Jul. Wilh. Brühl, Professor in the University of Heidelberg. Seventh Part, in conjunction with Eduard Hjett and Ossian Aschan, Professors in the University of Helsingfors; O. Cohnheim, O. Emmerling and E. Vahlen, Privatdocenten in the Universities of Heidelberg, Berlin and Halle. Pp. xxxii + 527. (Brunswick: F. Vieweg und Sohn, 1901.)

THE seventh part of the above text-book, which forms the ninth volume of the entire work, brings to a close the publication of that standard treatise of which two of the earlier volumes were reviewed in these columns on a former occasion (November 14, 1901, Supp. iii.). Beyond an indication of the contents of the present volume, there is not much to add in the way of general remarks to the statements already made. The whole work of translating and editing the early volumes and of writing the later ones has cost Dr. Brühl and his coadjutors five years' labour. As one result of the task which the editor first took in hand in 1896, chemical literature has been enriched by a series of valuable monographs written by specialists, these monographs, some of which were noticed in NATURE at the time of their appearance, being separate issues of certain sections of the present and former volumes. Chemists are no doubt familiar with the works on five- and six-membered heterocyclic systems (1898 and 1899), on vegetable alkaloids (1900) and on albuminoid substances (1900), all of which have originated in the manner indicated.

This concluding volume of the great treatise which first saw light in this country is one which appeals most particularly to physiologists. The four groups of compounds with which it deals are all, strictly speaking, and in the narrow sense, "organic," *i.e.* of vital origin. Dr. Cohnheim's contribution, "Die Eiweisskörper," is already known in its separate form; it occupies more than 300 pages of the volume. The same author contributes a section of some twenty pages on the compounds found in animal gall secretion. The third section, of more than 100 pages, comprises Dr. Emmerling's monograph on enzymes, and the concluding section, which is by Dr. Vahlen, deals with the ptomaines and toxines. It must be stated also that the present volume, in addition to its own subject-matter, contains a general synopsis of the contents and a general index for the whole seven volumes of the treatise on organic chemistry.

As regards the treatment of the subjects dealt with in this concluding instalment of the work, it need only be repeated that the names of the writers are vouchers for their completeness and accuracy. As compared with this and the volumes formerly noticed in these columns, the earlier volumes are, of course, now much behind our actual state of knowledge. But as standards fixed by the dates on the title-pages, these seven volumes represent the most complete and coherent descriptive treatise on the chemistry of the carbon compounds as yet offered to the scientific world. We shall be curious to see how our German colleagues will grapple with the literary difficulty of keeping a work of this exhaustive character *au courant* of the rapid progress which is being made in this department of science. As the editor reminds us in the preface, organic chemistry as a distinct branch of our science was born and has grown to its present magnitude during the nineteenth century. In congratulating Dr. Brühl and his collaborators on the completion of their task, we can assure him that there is every prospect of his wish that organic chemistry should develop as much during the twentieth as it has during the preceding century being fulfilled. We may further assure him that his hope that the work which he has been instrumental in giving to chemists may contribute towards this future development is amply justified. Of the original authors, one is happily still with us; to the memory of the other, this treatise will serve as an enduring monument. R. MELDOLA.

JAPANESE MYTHOLOGY.

Japanische Mythologie. Nihongi "Zeitalter der Götter." Von Dr. Karl Florenz. Pp. ix + 341; mit Illustrationen. (Tokyo, 1901.)

DR. FLORENZ is well known as a writer on Japan, and in his present work he adds one more volume to the many which he has published on that interesting subject. Some years ago he gave to the world the translation of a part of the "Nihongi," one of the earliest productions of Japanese literature, and in his present volume he takes the mythological portion of that work and by the aid of notes helps to throw considerable light on the very dark places of Japanese mythology.

The "Nihongi" yields in antiquity to only two other works, viz. the "Kiujiki," which was compiled in A.D. 620, and the "Kojiki," which was completed in 712. Eight years later the "Nihongi" was laid before the Empress Gemmiō as a complete work. The "Nihongi," or the "Records of Japan," is said to have been written by Shōtoku Daishi, and it is certain that only an author as well versed in Buddhist lore and Chinese classical literature as he was could possibly have written it.

To both of these wells of learning constant references are made, and throughout its pages the influence of Chinese thought is everywhere apparent. The opening sentence in the book contains the Chinese philosophical terms *Yin* and *Yang*, the male and female principles of Nature, which form a strange introduction to the mythology of a foreign land. The Chinese metaphor for the State, the temples of "The Earth and of Grain," also find frequent mention in its pages, and even a long dying speech originally uttered by the Chinese Emperor Kaotsu is put into the mouth of the Japanese sovereign Yūriaku. As Dr. Florenz says:—

"The little which European inquiry has hitherto been able to teach us of the real condition of Japan in the ancient times shows that the historical representation of this period in the 'Kojiki' and 'Nihongi' (upon which rest all the later statements of the Japanese) is most profoundly penetrated by false principles. The newer relations, partly developed from later material, partly influenced by Chinese culture, are reflected back upon the oldest without due distinction, and the result is a confused picture in which the critical inquirer can, it is true, frequently separate what is original from subsequent additions, but must often let fall his hands in despair."

The earliest part of the "Nihongi" consists of myths, pure and simple, and while it is necessary to sift the mass of legendary tales which it recounts for the grains of truth which it contains—and the grains are there—its value is enhanced by the poems of undoubted antiquity which are constantly introduced. This mythological period extends to the fifth century, and it is upon this portion of the history, with extracts from the "Kojiki," that Dr. Florenz has based his present work.

Japan is a land of myth. Of a more imaginative race than the Chinese, and enriched with the stores of legend gathered from the Malay Peninsula and the northern mainland of Asia, the Japanese have through all history revelled in the weird conceptions of the imagination, and even at the present day, unchecked by the veneer of civilisation which they have adopted, they see elves and fairies on every hill and in every valley, and recognise elfin foxes in moments of heightened fancy.

According to the "Nihongi," the creation of the world was after this wise, and here again we trace the influence of Chinese thought. In the beginning the universe was in a state of chaos, out of which by a process of disintegration the lighter and finer portions separated themselves from their surroundings and rising upwards formed the skies, while the more substantial constituents resolved themselves into the world. These two elements formed the male and female principles of Nature and begat certain deities, two of whom, Izanaki and Izanami, were the first to divide the land from the waters. We are told that these deities

"stood on the floating bridge of heaven and held counsel together, saying 'Is there not a country beneath?' Thereupon they thrust down the jewel spear of heaven and groping about therewith found the ocean. The brine which dripped from the point of the spear coagulated and became an island, which received the name of Onogoro," *i.e.* self-curdled.

This legend is interesting as reminding us of the Greek myth of Dêlos, *i.e.* Manifest, which was so called from its suddenly emerging from the sea. Dêlos was, as will be remembered, the centre or hub of the Cyclades, which derived their name, ἀπὸ κύκλου, from the wheel. Another and a still more striking parallel is furnished by the account which relates that "Poseidon with one blow of his trident made the island surge from the bottom of the ocean." In other lands besides Greece we recognise this legend under varying forms, and, indeed, on almost every page of Dr. Florenz's work we find traces of world-wide myths. One of the most widely spread of these is that of St. George and the Dragon. Sosa no wo no Mikoto in this case represents the Christian St. George and Kushi-nada-hime is the lovely maiden whom he rescues from the fangs of the serpent or dragon.

To the comparative mythologist Prof. Florenz's work will be invaluable. But, as it professes to be, it is essentially a book for the student of folk-lore. By such it will be found full of suggestive matter, while it is much to be feared that to the ordinary reader it will be but a weariness to the flesh.

OUR BOOK SHELF.

An Introduction to Chemistry. By D. S. Macnair, Ph.D., B.Sc. Pp. xii + 187. (London: George Bell and Sons, 1902.) Price 2s.

WHATEVER may be thought of the use of text-books in teaching elementary science, there can be no doubt as to the improvement which has taken place in the character of such books in recent years. The change is particularly noticeable in volumes dealing with the rudiments of chemistry and physics. Instead of the descriptive style formerly in vogue, we have now courses of practical work connected with a few explanatory paragraphs, and the whole constructed upon a plan which aims at making the pupil do things for himself and so far as possible arrive at his own conclusions.

Dr. Macnair's book is based upon this method, and as a representative of a good type it deserves a welcome from teachers of science. Beginning with simple observations and experiments on solubility, the author paves the way to the study of the rusting of iron, the atmosphere, water, chalk and a few other common bodies, following in a general way the course suggested by Prof. Armstrong, which is now followed in many schools, with results encouraging both to teachers and pupils.

As to the educational value of work of the kind described by Dr. Macnair, no one who has tried it with young pupils desires to go back to the old method of teaching chemistry by test-tubing in the laboratory and startling experiments in the lecture room. Quantitative work which was formerly postponed until pupils were able to make an analysis of a simple salt is now taken up at the beginning of a course, and early use is made of squared paper for plotting results. Dr. Macnair, for instance, shows on his twelfth page how solubility curves should be constructed from results of experiments.

To anyone familiar with the excellent work now being done in schools, by the practical study of common properties of matter, the book adds little that is new, and many of the experiments will be recognised. But this does not make the book any the less useful as a practical manual containing a course of work suitable for introducing pupils to methods of scientific study.

A Tentative List of the Flowering Plants and Ferns for the County of Cornwall, including the Scilly Isles. By F. H. Davey. Pp. xvi + 276. (Penryn: F. Chegwidden, 1902.)

THE spirit in which Mr. F. H. Davey has taken up the task of preparing a "Flora of Cornwall," which shall rank with Druce's "Flora of Berkshire" and other similar handbooks bodes well for success. In two years and a half this tentative list has been formulated, and as one looks through the list of species and records there is ample proof of excellent work. The principle of the book is to give the first record for each species, besides a complete list of localities for species and varieties. Also it is sought to amplify the published list of plants found in Devon, but wanting in Cornwall, and to obtain details of local peculiarities of growth, as well as local names or any plant lore which can be unearthed. In the book

before us these features are not treated, but presumably in the "Flora" they will be incorporated. Also it would add to the interest of the book if a summary of the principal ecological features were presented. It is evident from the published list of contributors that Mr. Davey has been successful in enlisting the services of many well-known systematists; but more workers are required, especially residents in the districts just north and east of Truro, also in Camborne and the country lying south. To these and to botanists visiting the county Mr. Davey will gladly supply copies of "the tentative list," which is interleaved for notes, so that their records may be returned to him in November, 1903, when the accumulated data will be worked up.

Outer Isles. By A. Goodrich-Freer. Pp. xv + 448. (Westminster: Constable and Co., Ltd., 1902.) Price 12*s*. 6*d*. net.

THIS book contains much valuable information about the Outer Hebrides and their people, and it is good service to have it put on record in accessible and readable form. Specially good are the accounts of the *Ceilidh*, or custom of "assembling together during the long winter nights to pass them off in happiness and mirth," and of the process of "fulling" or dressing the Harris cloth. But the work as a whole is blemished by a want of perspective. The natives of the Outer Isles are, after all, not without faults, and even vices, and some of their virtues are shared by inhabitants of the "adjacent islands of Great Britain and Ireland." There is something to be said on the side of the landlord, the Free Kirk, and even the sporting Sassenach, and the reiteration of their enormities on all possible occasions becomes very tiresome. It is not true that the people of the Outer Hebrides are "practically less known to the average Englishman than the inhabitants of New Zealand or of Central Africa," or that "those who penetrate to their islands, so far at least as they are represented by comfortable inns in easily accessible places, come back knowing nothing of the life of the people, and only ready to condemn them as half-savage, extortionate, and above all, idle."

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. Rhynchota, vol. i. (Heteroptera). By W. L. Distant. Pp. xxxviii + 438. (London: Taylor and Francis, 1902.)

THIS important work continues to make steady progress, and we have now the pleasure to notice the appearance of another volume devoted to entomology, in addition to those already published by Sir G. Hampson on "Moths," Col. C. T. Bingham on "Hymenoptera" and Mr. R. I. Pocock on "Spiders." Mr. W. L. Distant is so well known as a close student of Rhynchota, and also for his careful and accurate work, that we have no doubt that specialists will find the present volume to be one of the most complete and satisfactory that has yet appeared on the subject; and it should give a great impetus to the study of Rhynchota, especially in India and in the adjacent countries.

Following Severin, Mr. Distant accepts fifteen families, eleven of which are represented in India, the first volume including descriptions of the Pentatomidæ, Coccidæ and Berytidæ. We may point out that Dr. D. Sharp's estimate of about 18,000 species of Rhynchota, quoted by Mr. Distant on p. xxxv, is obviously much too low, the number given by Mr. W. F. Kirby as long ago as 1892, in the second edition of his "Elementary Text-book of Entomology" (p. 14), being already 18,300. The volume is illustrated by 249 excellent text illustrations by Mr. H. Knight, including a series of very clear illustrations of structure in the introduction.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Carnegie Institution of Washington, D.C.

SIR,—It gives me great pleasure to answer in writing some of the questions which you, and others who are interested in scientific research, have asked in respect to the scope of the institution lately founded in Washington by Mr. Andrew Carnegie.

To begin with, it may be well to recapitulate the facts already made known. The amount of his gift is ten million dollars (2,000,000*l*.), so invested that the annual income is five hundred thousand dollars (100,000*l*.). The control of this fund is invested in a board of twenty-seven trustees, selected from widely separated parts of the United States, and including many men who have won distinction and confidence by the service they have rendered in public life. It is not a board made up of specialists, but rather (if I may be allowed the expression) of generals—that is to say, of men accustomed to the administration of large affairs, political, financial, philanthropic and educational. Absolute power is given to this board to devise such methods and form such plans as may seem to them wise in order to carry out the purposes of Mr. Carnegie. These purposes he has clearly defined in the deed of trust and, with less formality, in the remarks which he addressed to the trustees when they first came together on January 29, 1902, under the chairmanship of the Hon. John Hay, Secretary of State, and recently the Ambassador of the United States in London.

In one general phrase, which reads as follows, Mr. Carnegie thus lays down the principle which has guided him:—"It is proposed to found in the city of Washington an institution which, with the co-operation of institutions now or hereafter established there or elsewhere, shall in the broadest and most liberal manner encourage investigation, research and discovery, show the application of knowledge to the improvement of mankind, provide such buildings, laboratories, books and apparatus as may be needed, and afford instruction of an advanced character to students properly qualified to profit thereby."

There are six points upon which the munificent donor then proceeds to lay emphasis, and these are, namely, the promotion of original research; the discovery and encouragement of exceptional men; the increase of facilities for higher education; the assistance of those now engaged in research; the bringing to Washington of students qualified to profit by the work carried on in the several departments of the Government; and finally, the publication of scientific memoirs.

So far all was clear. Mr. Carnegie's part was performed. Now began the perplexities and responsibilities. The trustees, many men of many minds, must take the subsequent steps. Fortunately, there was no occasion for hasty action; at the outset no buildings were to be constructed, no faculty was to be brought together. Such considerations could be postponed indefinitely. The trustees decided to take time for reflection and for conference with the leaders of science at home and abroad, before the adoption of a programme. Letters were addressed to many persons who could not be reached in person. Confidential interviews were secured with those who could be seen in Europe and the United States. The experience of existing institutions was studied, such as the Royal Society, the Royal Institution, the Academies of Science in Berlin, Munich, Vienna, Paris and other cities. Attention was given to the conditions which have helped or retarded the progress of eminent men during the last generation

—Darwin, Pasteur, Helmholtz, Abel and Virchow for example, in Europe—Henry, Agassiz, Dana and Rowland in America—and also the encouragements and discouragements which are encountered by the men of to-day. Time will be required for the digestion of this material in order to discover the methods which are most efficacious in the advancement of knowledge.

Meanwhile, much co-operative counsel will be given by experts in various branches of learning. As soon as the general purposes of Mr. Carnegie's foundation were made known, hundreds of applications for assistance were received—the number of self-discovered "exceptional men" was large. The number of trivial applications for help in the prosecution of researches was surprising; but, on the other hand, the number of well-considered, important, fundamental inquiries suggested by men of the highest rank among the promoters of knowledge indicated that the entire income would all be absorbed at no distant day. Discrimination, therefore, became the paramount virtue—discrimination which should meet the approval and, if possible, the concurrence of the world's wisest men.

For this discrimination, the aid of specialists was indispensable. The astronomer was not the man to judge of biological claims, nor the chemist of economic problems. No board of "generals" could wisely act without the aid of a strong advisory staff of "adjutants." Accordingly, the authorities of the Carnegie Institution proceeded to select and enlist a number of advisory committees. Three, four, or five well-known authorities were chosen in each of the principal branches of science. All their expenses for travel and for clerical assistance were generously paid by the fund, but their services, like those of the trustees, were cheerfully given to the public without remuneration, and often at the sacrifice of time and convenience. Their hearty co-operation is a fresh illustration of the public spirit of men of science in our day, and their readiness to appreciate and help on the most deserving claims, irrespective of local or personal preference, augurs well for the efficiency of the Carnegie Fund and for the wisdom of the plans that will presently be adopted.

More specific announcements cannot be made until the trustees come together for their second meeting at the close of November next.

A careful perusal of Mr. Carnegie's language will bring out several points, to some of which I will venture to call attention. Here we have that special "endowment for research," which has been during the last thirty years and more the desire of so many men in England and America. This endowment is independent of any existing academy, university or school of technology; but it may co-operate with any that now exist or that may be established. It does not establish a university in Washington, which so many have advocated and so many have disapproved. Mr. Carnegie on this point is explicit and decided. The efficiency of the new institution is not restricted by any local, political or ecclesiastical fetters. Nor is there any attempt to decide what science includes. None of the progressive organised and systematic branches of knowledge are excluded. Economic, historical and archæological inquiries may be aided as well as those which are more obvious to the public—physical, chemical, biological, geological and astronomical researches. Education may be encouraged, but it must be by the personal development of uncommon talents,—the advanced student, the young professor, "the exceptional man." To the last clause of his deed of trust, Mr. Carnegie attaches the highest importance. It corresponds with a clause in his gift to the Scotch universities The trustees by a majority of two-thirds "may modify the conditions and regulations under which the funds may be dispensed"—if time, experience and changed conditions call for new arrangements.

I cannot close this letter without reference to the great interest which this gift has aroused in all scientific circles at home and abroad. During the past summer, spent upon the Continent and in Great Britain, I have had the honour of talking with many men of eminence, everywhere known as investigators, and their counsel, suggestions and co-operation are not only an indication of the international character of science, but they give an assurance that the most enlightened experience of the world can be enlisted in the plans of this new foundation. At home, "it goes without saying," that there is the heartiest response to Mr. Carnegie's generosity.

With a grateful appreciation of the work of NATURE in the persistent advocacy of research. DANIEL C. GILMAN,

London, September 9. President of the Carnegie Institution.

Re Vegetable Electricity.

WITH reference to Dr. Waller's letter in NATURE, September 18, I confine my reply, in the limited space courteously offered me, to the main issue, *i.e.* the priority of research on the electric response of ordinary plants under mechanical stimulus. My footnote to my Linnean Society paper gave the published dates which must determine, as usual, such a question. It would only obscure the issue were I to take up here assertions resting solely on Dr. Waller's personal affirmation.

My statement which Dr. Waller wishes to traverse is definite enough, and may be answered in a definite manner. He has not done this. I stated that five months before the communication of his paper to the Physiological Society (November 9, 1901), Dr. Waller *heard* me describe my results on the electric response of ordinary plants under mechanical stimulus. My paper on the "Electric Response of Inorganic Substances: Preliminary Notice," was communicated to the Royal Society on May 7, 1901 (*i.e.* six months before Dr. Waller's communication to the Physiological Society). I read it before the Society on June 6. From the concluding portion of this paper I quote the short summary of the results obtained with plants.

"An interesting link between the response given by inorganic substances and the animal tissues is that given by plant tissues. By methods somewhat resembling that described above, I have obtained from plants a strong electric response to mechanical stimulus. The response is not confined to sensitive plants like mimosa, but is universally present. I have, for example, obtained such response from the roots, stems, and leaves of, amongst others, horse-chestnut, vine, white lily, rhubarb and horse-radish. The current of injury is, generally speaking, from the injured to the uninjured part. A negative variation is also produced. I obtained both the single electric twitches and tetanus. (Two response curves given to exhibit this.) Very interesting also are the effects of fatigue, of temperature, of stimulants and of poison. Definite areas killed by poison exhibit no response, whereas neighbouring unaffected portions show the normal response."

Dr. Waller not only heard me describe these results, but took part in the subsequent discussion of my paper. It is indeed very strange that he should on that occasion have said absolutely nothing about his being engaged in this particular investigation. An eminent physiologist declared during the discussion that the electric response of ordinary plants under mechanical stimulus was an impossibility. Dr. Waller, who immediately followed him, it is again remarkable to note, had not one word to say for the possibility of such a phenomenon! These facts are as significant as the fact that Dr. Waller communicated his paper five months after he had discussed mine at the Royal Society.

The above will dispose of the question of priority. My Linnean Society paper and Dr. Waller's paper read before the Physiological Society are now before the public. From these, anyone interested in the subject will be able to determine the scope of the two investigations, the novelty of the appliances and methods employed, and the accuracy of the results obtained.

JAGADIS CHUNDER BOSE.

THE claim for priority comes from Prof. Bose—implicitly by the note to his paper at the Linnean Society, to which I had to demur—explicitly in his present reply. Prof. Bose bases his claim on the final paragraph of a paper of June 6, 1901, now in

the Archives of the Royal Society. If this be regarded as a valid document and date of departure, I shall have something more to say about Prof. Bose's methods. If this date and document be not valid, his claim rests upon a paper at the Linnean Society of July 21, 1902, which seems to me to be a very interesting instance of scientific mimicry. Anyone interested in the study of such phenomena will find it instructive to compare the papers mentioned by Prof. Bose, of November 9, 1901, and July 21, 1902, to the Physiological and Linnean Societies respectively. I think he should also, as regards the general method, consult my Lectures on Animal Electricity of 1897 at the Royal Institution, which have been adopted by Prof. Bose as his point of departure.

A. D. WALLER.

British Association Meetings.

THE gradual decrease in the number of those attending the recent meetings of the British Association might suggest that the popularity or the usefulness of these scientific gatherings is on the wane. The opportunity for an instructive comparison exists in the fact that on the last three occasions on which the Association has met, it has repeated its visits to well-known centres, widely distributed. It might have been anticipated that, owing to the growth of material prosperity and of the population of these towns, a continually increasing number would have availed themselves of the advantages of these meetings. The following figures show, however, that the contrary is the case:—

Year.	Place of Meeting.	Number attending.	Year of previous Meeting.	Number attending.
1900	Bradford	1915	1873	1983
1901	Glasgow	1912	1876	2774
1902	Belfast	1620	1874	1951

Naturally the amount of grants for scientific purposes shows a similar decline:—

Bradford,	1072*l.*	against 1685*l.*	in 1873
Glasgow,	945*l.*	,, 1092*l.*	,, 1876
Belfast,	960*l.*	,, 1151*l.*	,, 1874

The usefulness of the Association in one direction is apparently lessened, since it has distributed about 1000*l.* less in the three years, but it may be that there is not the same necessity for assistance as was the case a quarter of a century ago, and that consequently the amount applied for by the different sections has not been as large as on previous occasions. But this does not put aside the fact that there is a distinct falling off in the interest exhibited, as tested by the numbers attending.

Supposing there is any decrease in the popular favour, and the smaller figures are not due to temporary causes, it seems worth while to ask whether any portion of the decline is traceable to reasons connected with the Association itself. This is a question which can be answered only by those who are intimately connected with the management, but there was a feeling among some of the members that the business was unduly protracted, and it was asked, with some apparent show of reason, why the meeting must always begin on a Wednesday. If the President's address, it was urged, was given on Monday evening, it would allow four clear, uninterrupted days for the business of the sections, which in most cases would be found sufficient, and then the Saturday could be employed in the manner it now is, or in winding up the unfinished sections. There may, of course, be an insurmountable objection to altering the arrangements which have existed for so many years, but which scarcely seem to meet the conditions of modern life, and it is with the view of hearing from some authoritative source the object of maintaining the old order of things that I have ventured to trouble you with this note.

September 19.

Helmholtz on the Value of the Study of Philosophy.

THE opinions of Helmholtz, even as expressed in his *popular* scientific lectures, have such permanent weight that you may consider the following correction of sufficient general interest to publish it in your journal.

On p. 234 of Dr. Atkinson's "Popular Lectures on Scientific Subjects by H. von Helmholtz" (second series, new edition, Longmans, Green and Co., 1893), lines 7 to 11, we read:—

"And the physician, the statesman, the jurist, the clergyman, and the teacher, ought to be able to build upon a knowledge of *physical* processes if they wish to acquire a true scientific basis for their practical activity." (The italics are mine.)

What may have been Helmholtz's opinion of the value of a knowledge of *physical* science to the groups of specialists above named may be gathered from other parts of his writings, but in view of the surely unjust discredit into which the study of genuine philosophy (such as Helmholtz defines it) appears to have fallen in the eyes of the followers of the "Naturwissenschaften," it would appear just to quote the original passage, whereby it will be seen that what was perhaps a printer's error in the translation has altered the whole gist of the passage:—

"Und auf die Kenntniss der Gesetze der *psychischen* Vorgänge müsste der Arzt, der Staatsmann, der Jurist, der Geistliche und Lehrer bauen können, wenn sie eine wahrhaft wissenschaftliche Begründung ihrer praktischen Thätigkeit gewinnen wollten" (Helmholtz, "Vorträge und Reden," p. 189, fourth edition, second vol., Braunschweig, 1896). (The italics are mine.) That "psychischen" is *not* a printer's error for "physischen" in the original is evidenced by the context, which is so interesting that I venture to quote it. After a brief comparison of the relation of philosophy to metaphysics with that of astronomy to astrology, Helmholtz says:—

"Ebenso bleibt der Philosophie, wenn sie die Metaphysik aufgiebt, noch ein grosses und wichtiges Feld, die Kenntniss der Geistigen und seelischen Vorgänge und deren Gesetze. Wie der Anatom, wenn er an die Grenzen des mikroskopischen Sehvermögens kommt, sich Einsicht in die Wirkung seines optischen Instrumentes zu verschaffen suchen muss, so wird jeder wissenschaftliche Forscher auch das Hauptinstrument, mit dem er arbeitet, das menschliche Denken, nach seiner Leistungsfähigkeit genau studiren müssen. Zeugniss für die Schädlichkeit irrthümlicher Ansichten in dieser Beziehung ist unter Anderem das zweitausendjährige Herumtappen der medicinischen Schulen."

I have not access to earlier editions of the original German than 1896; relatively to my object, such reference seems unnecessary.

Trade Statistics.

DR. MOLLWO PERKIN repeats in NATURE, p. 443, Mr. Levinstein's statement that in foreign trade "we went back during the ten years 1891–1900" (*Journ.* Soc. Chemical Industry, pp. 893–4). The evidence given is that "in the year 1890 our total exports amounted to 328 millions sterling," whereas "the average amount during the decade 1891–1900 was only 300 millions." But why should 1890 be taken as the standard year? It happens that the exports in that year were unusually high—higher, indeed, than in any other year from 1880 to 1898. Had Mr. Levinstein been in a hopeful frame of mind, he might have chosen 1888 or 1892 as his normal year, or, much more rationally, he might have taken the average of five years, 1886–1890 (299 millions), or the average of ten years, 1881–1890 (297 millions). Any of these methods would have brought out the more pleasing conclusion that our foreign trade is advancing. My object is not to decide whether it is or not, but to protest against Mr. Levinstein's method of proof. Can we imagine a meteorologist contrasting the average rainfall of a series of years with the rainfall of a *single* preceding year and on that basis announcing a change in the climate?

The facts (often exaggerated and misunderstood) as to the more rapid advance of German exports are fully and clearly stated in "Comparative Statistics of Population, Industry and Commerce," recently issued by the Board of Trade at the price of $5\frac{1}{2}$*d.* It is not clear why Mr. Levinstein makes use of the British "total" exports, including all the transit trade, while for Germany he takes the "special" exports, from which the transit trade is, as far as possible, excluded. This swells all the British amounts by something like 25 per cent. beyond what they would stand at if they represented native produce only. It does not, however, much affect comparisons of rates of progress. But it confuses abstractors—in Dr. Perkin's abstract the distinction is overlooked.

F. EVERSHED.

Kenley, Surrey, September 9.

IT is quite true, as Mr. Evershed points out, that the exports for 1890 were unusually high, but those of 1899 and 1900 were also exceptional, owing largely to war exports; this, however, hardly alters Mr. Levinstein's contention—that the trade of the country shows a decline as compared to the trade of

Germany and the United States. But if, instead of using Mr. Levinstein's figures, we take the annual exports per head of population, which is after all the truest test, we find that in the period 1870–74 they were 7*l.* 7*s.* 3*d.* per head, but in 1895–99 they had fallen to 5*l.* 19*s.* 5*d.* In Germany during the same periods they were 2*l.* 16*s.* 7*d.* and 3*l.* 7*s.* 2*d.* respectively, while in the United States they rose from 2*l.* 9*s.* 11*d.* to 2*l.* 18*s.* 4*d.* These figures show that although per head of population we export more than either of these nations, yet during the last forty years they have been increasing their exports per head, but those of the United Kingdom have been declining. The figures are much more striking if at the same time we examine the increase of population which has taken place in the three lands during the same period. From 1871 to 1901, the population of the United Kingdom increased by 31·7 per cent., while that of Germany increased 37·3 per cent. and that of America 96·1 per cent.[1]

I will now take another comparison—the five years' averages of the annual exports at the beginning and end of the period 1880–1900. Here it will be seen that the increase of exports of the United Kingdom only amounted to 6·4 per cent. (234 to 249 millions), but that Germany showed an increase of 23·1 per cent. (156 to 192 millions) and the United States 42·8 per cent. (166 to 237 millions).

Again, we are unable to show such large increases in the quantity of pig iron produced as are Germany and America. In the years 1870–74, the United Kingdom was far and away ahead of all other nations, producing 6·4 million tons against 1·8 million tons by Germany and 2·2 million tons by America. But in 1896–1900, the amounts were for the United Kingdom 8·9, Germany 7·4, and America 11·5 million tons.

Mr. Evershed objects to Mr. Levinstein taking a "fat year" as the starting point for his statistics, but, as I have already pointed out, the years 1899 and 1900, which come within Mr. Levinstein's decade, were also exceptionally good years and thus help to bring up the average. But I think that although Mr. Evershed has taken exception to the use of the year 1890, he will agree with all scientific and broad-minded men in being glad that a man of Mr. Levinstein's experience should have the courage to speak out and try to wake the nation up to a sense of its responsibilities.

F. Mollwo Perkin.

Bipedal Locomotion of Lizards.

I kept for many years in a glass case some specimens of *Lacerta viridis*, and often observed them after a feed playing in the sunlight in a peculiar manner, first drinking water, which they lapped up with their wide forked tongues. The play was a sort of dance. The lizard stands on his hindlegs and, raising the fore part of his body, executes a rapid, playful waving of the forelegs. When both forelegs are used, they move in unison; sometimes, however, only one is employed. This action seemed to be meant as an attraction, the motions being performed facing another lizard, who often responded with answering waves of the forelegs; at times during the pastime, the pair would lick each other. I observed the females indulged oftenest in this coquettish dance, though the males would go through the same performance, strange to say, as often with each other as with a female for a partner to set to.

One female I kept for five years always, when excited, took a perpendicular position, progressing on her hindlegs with the fore part of the body lifted, and would play, running at my hand and biting, always in that erect pose.

The blue lizards of Capri, which I have kept for years in confinement, move along upright under excitement, also using bipedal action.

Rose Haig Thomas.

September 23.

RUDOLPH LUDWIG KARL VIRCHOW.

"All that lives must die,
Passing through nature to eternity."

THE great master and founder of modern pathology, Rudolph Virchow, has passed away, full of years and full of honours, mourned, not only by his fellow countrymen, but by the whole scientific world. A fall early in January last resulting in a fractured thigh was the ultimate cause of his death, which occurred on September 5.

[1] In Germany and America, the census returns are for 1900.

Born at Schilvelbein in Pomerania in 1821, Virchow attended the public school of his native town until his thirteenth year, when he entered the gymnasium of Cöslin and early distinguished himself by his linguistic attainments. In 1839, he entered the Friedrich-Wilhelm Institut, a training college for army medical officers, having among his teachers Müller and Caspar and among his fellow students Helmholtz, and in 1843 proceeded to take his degree. He had already shown such promise that he was released from service with the army and was attached to the Charité Hospital as prosector of anatomy, acting as assistant to Froriep, whom he succeeded in 1846. About this time he founded, in collaboration with Reinhardt, the famous *Archiv*, and after the death of the latter continued to edit it himself. In 1848, he carried out an investigation into an epidemic of relapsing fever in Silesia, and so uncompromising were his strictures on the authorities, together with his alliance to the ultra-Radical party, that he was compelled to resign his appointment at the Charité. Already, however, his reputation as a pathologist was made, and he was immediately offered and accepted the chair of pathology at Würzburg, where for the next seven years he devoted himself to pathological research. In 1856, on the death of Hemsbach, the Faculty of the University of Berlin petitioned for his recall, and, in spite of bitter opposition, was successful in its application, and Virchow returned to his old University for the remainder of his life, founding the Pathological Institute and the Museum of Morbid Anatomy.

Virchow's life was a strenuous one, and being blessed with a wonderful constitution he was able to devote himself to, and to become a master in, many pursuits, any one of which is usually sufficient to fill the life of ordinary mortals. In addition to his pathological chair, the duties of which he fulfilled up to the time of his accident, he was ethnologist and anthropologist, archæologist and Egyptologist, politician, a member of the Berlin Municipal Council for forty years, a member of the Prussian Chamber from 1862 to 1878, where he was the recognised leader of the Radical party and for fifteen years chairman of the Finance Committee. In 1880, he was elected a member of the Imperial Reichstag, but took little active part in its debates. One of his most important public works was concerned with the introduction of a system of drainage and with the installation of sewage farms, whereby Berlin has become one of the healthiest cities of Europe.

Of the man it may be said that he was beloved by his family and by his intimates. Short of stature and spare of figure, with grizzled hair and piercing grey eyes covered with spectacles, his was not a striking personality. Nor was he an orator, having a somewhat thin and weak voice and impassive delivery, but what he said was always to the point and clothed in simple but logical language, and he compelled a hearing by his very earnestness and simplicity. His political views and his uncompromising manner of stating them unquestionably prevented a full measure of State recognition of his genius.

As a teacher he attracted students from all parts of the world. Until his time, autopsies had been performed in a very perfunctory manner, the supposed seat of disease alone being examined. Virchow, however, submitted all the organs and tissues to a careful scrutiny, thereby in course of time as data accumulated proving the interdependence of one condition upon another and showing how widespread might be the effects of a limited lesion. At his demonstrations, the specimens were subjected to a rapid description and criticism, rough sections were cut and placed under the microscope, which was mounted upon a trolley running on rails, and so could be submitted without disturbance to the scrutiny of each member of the class. Drawings of the specimens

were made upon the blackboard and the salient features indicated, and in the course of a demonstration six or eight specimens might thus be started on the tour of inspection.

Of his pathological work, the earliest was upon vascular disorders. He was the first to elucidate the true nature of phlebitis, thrombosis and embolism, to recognise the essential features of leukæmia and to distinguish this condition from pyæmia, so laying the foundation for the brilliant work of Ehrlich and others upon hæmatology. In 1858, his "Cellular Pathology" appeared, in which the theory that every cell arises from a pre-existing cell was enunciated and the cellular derivation of the connective tissues, bone and cartilage recognised. Up to this time, the humoral theory had dominated medicine, but these considerations revolutionised pathology by introducing the new conception that all pathological cell-formations must arise from pre-existing normal cells. He says in his lectures, "The question is whether the general types which we have established for the physiological tissues will also be found to hold good for the pathological ones. To this I unreservedly reply, yes; and however much I herein differ from many of my living contemporaries, however positively the peculiar (specific) nature of many pathological tissues has been insisted upon during the last few years, I will nevertheless endeavour to furnish you with proofs that every pathological structure has a physiological prototype and that no form of morbid growth arises which cannot in its elements be traced back to some model which had previously maintained an independent existence in the economy."

Harvey had enunciated the celebrated proposition *Omne vivum ex ovo*, subsequently found to be too narrow to apply to all living forms; to Virchow pathology and physiology are indebted for the not less striking dictum, *Omnis cellula e cellulâ*. By this his name will live through the ages. Another great work of his was that on tumours, unfortunately never completed. He showed that cartilaginous tumours of bone might start from islands of cartilage which had remained untransformed during the general ossifying process, and thus gave some support to Cohnheim's theory of the origin of tumours from embryonic remains. He further made contributions on tuberculosis and leprosy, trichiniasis, hydatid tumours of the liver, lardaceous disease, cholera and diphtheria, and animal pigments; in fact, it is no exaggeration to say that there is hardly any subject in pathology that has not been illumined by some important contribution of his. He was a pathological anatomist and histologist rather than an experimental pathologist, and pathological bacteriology was of too recent development for him to contribute to it extensively. It is true that he made mistakes—he was but mortal; for example, his theory of the dependence of chlorosis upon anatomical defects in the circulatory organs has been found untenable—but he was the first to recognise them, and as often as not himself destroyed the fabric he had previously erected.

Virchow's fame was world-wide, and honours of all kinds were showered upon him. In 1874, he became a member of the Royal Academy of Science of Berlin; at the centenary of the Institute of France he was made a Commander of the Legion of Honour, and the following year Foreign Associate of the French Academy of Sciences. A foreign member of our Royal Society, he was Copley medallist in 1892 (an honour he highly appreciated) and Croonian lecturer in 1893. The subject of his discourse, delivered in English, on this occasion was "The Position of Pathology among the Biological Sciences" (NATURE, vol. xlvii. p. 487). In 1898, his last visit to us, he delivered the Huxley lecture at Charing Cross Medical School, and he was afterwards entertained at a banquet, at which Lord Lister presided. The title of the Huxley lecture was "Recent Advances in Science and their Bearing on Medicine and Surgery," and to the last he retained his marvellous vitality of mind and kept abreast of the most recent advances in pathology. Last year, on the occasion of his eightieth birthday, he was the recipient of congratulatory addresses from all parts of the world, Lord Lister representing the Royal Society and other learned bodies of Great Britain and Ireland, and his reply, which occupied nearly two hours in delivery and was brimful of dates and facts, was given without a note.

His countrymen rightly accorded him a public funeral, and representatives of the State, the city, the university and of the learned societies accompanied his remains to their last resting place.

Space forbids anything but this brief sketch of Virchow's life, but as a writer in the *Lancet* well says, "His active work ceased only with his death, the world's appreciation of his worth remains."

R. T. H.

THE ABEL FESTIVAL IN CHRISTIANIA.

THE centenary of the birth of the famous Norwegian mathematician Henrik Niels Abel was celebrated in Christiania by a festival, or rather a series of festivals, which lasted from September 4 to 7, to which delegates from all the more important scientific societies and universities of the world were invited. The festival aroused the interest of the people of Christiania in a very unusual degree and, indeed, appeared to be regarded in the light of an important national event; the presence of the King of Sweden and Norway, who made a special journey from Stockholm for the purpose, contributed in a high degree to emphasise the importance attached to the festivities by the whole population of the Norwegian capital. The festival was inaugurated by an informal reception of the delegates at a supper-party given on the evening of September 4 at St. Haushangen, a place of popular resort on the outskirts of Christiania. The company was received by the famous Arctic explorer, Dr. Nansen, president of the reception committee, by the Foreign Minister Lagerheim, the Ministers of State Blehr and Ovam, the president of the Storthing, and Prof. Mohn, president of the Christiania Academy of Science. In a bright and genial speech delivered in English, Dr. Nansen welcomed the foreign delegates and expressed the feeling of pride on the part of his own small nation in having through Abel made an important contribution to the essentially international work of the development of science and of civilisation. The formal part of the festival commenced at noon on September 5 in the Hall of the Municipality; the King and his son Prince Eugen arrived shortly after noon, and were received by a guard of honour, consisting of students of the University of both sexes. The ceremony consisted of the performance of a cantata written by the celebrated author Björnson, and of speeches which were made between the first and second parts of the cantata. Speeches were delivered by the Minister of State Blehr in French, by Prof. W. C. Brogger in German, and on behalf of the delegates by Prof. H. Weber, of Strassburg, and Prof. Volterra, of Rome. A detailed appreciation of Abel's work was given by Prof. L. Sylow. In the evening, the delegates had the honour of being invited by the King to a reception and supper at the Castle, when a large and distinguished company was present; many of the delegates were presented to the King, who conversed freely with them in their own languages. The second part of the festival was held on September 6, at noon, in the Hall of the University, the King and Prince Eugen being again present. The proceedings commenced with an address in French by Prof. Mohn. Speeches were then delivered by Prof. Forsyth on behalf of the English-speaking delegates; by Prof. Gravé on behalf of the Slav nations; by Prof. Picard, Prof. Schwarz, Prof. Zeuthen, Prof. Henzel

and Prof. Mittag-Leffler. The eloquent speech of Prof. Forsyth met with the special approval of the audience and of the Christiania Press. The addresses from the various universities and learned societies were then delivered by the delegates; these were so numerous that with a few exceptions the delegates handed them in with a simple statement of the name of the society or university from which they came.

The last stage of the proceedings consisted of the conferring of honorary degrees upon twenty-nine distinguished men of science, of whom ten were present as delegates. It was explained that the University of Christiania had hitherto not possessed the power of granting honorary degrees, but that by a special Act of the Storthing the power had been granted to the University with a view to the present occasion. Among the twenty-nine mathematicians who were created *Doctores Mathematicae*, there were six British subjects—Lord Kelvin, Lord Rayleigh, Dr. Salmon (provost of Trinity College, Dublin), Sir George Gabriel Stokes, Prof. G. H. Darwin and Prof. A. R. Forsyth. In the evening, the delegates and a large number of other guests were entertained at dinner by the Municipality of Christiania; after the dinner there was a torch-light procession of many hundreds of students, which produced a most imposing effect. The students were addressed from an open window by Dr. Nansen in an enthusiastic speech. The festival concluded with a special representation of Ibsen's *Peer Gynt* at the National Theatre on the evening of September 7, the King and a distinguished company being present. The University of Oxford was represented by Prof. A. E. H. Love, F.R.S., the University of Cambridge by Prof. A. R. Forsyth, F.R.S., the University of Dublin by Prof Joly, the University of Durham by Prof. Sampson, the University of London by Prof. A. G. Greenhill, F.R.S., the University of Glasgow by Prof. Jack, the London Mathematical Society and the Cambridge Philosophical Society by Dr. Hobson, F.R.S.

MR. F. W. RUDLER AND THE MUSEUM OF PRACTICAL GEOLOGY.

MR. F. W. RUDLER retired under the age regulations at the end of last month from the post of curator and librarian of the Museum of Practical Geology. He entered the public service in 1860 as assistant to Trenham Reeks, who was then curator of the Museum and registrar of the School of Mines. For fifteen years Mr. Rudler was actively engaged in the Museum, acquiring an intimate knowledge of mineralogy and applied geology, and an expert knowledge of British pottery. He practically re-wrote the third and fourth editions of the "Descriptive Guide to the Museum," which was originally drawn up by Robert Hunt; and he almost wholly prepared the second and third editions of the "Catalogue of Specimens of British Pottery and Porcelain."

In 1876, Mr. Rudler was chosen professor of natural science in the newly-established University College of Wales at Aberystwyth. Here he was successfully occupied for three years, until on the death of Mr. Reeks he was besought by the late Sir Andrew Ramsay to apply for the post rendered vacant in the Museum of Practical Geology. Mr. Rudler's appointment was cordially assented to, and from 1879 onwards he has held office with increasing advantage to the Institution and to the many individuals who have constantly sought his advice. It is not too much to say that one might search the world over and fail to find anyone with a fuller knowledge of the subjects that have been connected with the Library and Museum of Practical Geology, or one who was more ready at all times to give to others the benefit of varied and accurate information.

NOTES.

A COMMITTEE has been formed, under the chairmanship of Prof. Waldeyer, for the erection in Berlin of a public memorial of the late Prof. Virchow.

DR. DAVID FERRIER, F.R.S., will deliver the Harveian oration before the Royal College of Physicians, London, on October 18.

WE are sorry to have to record the death, at the age of sixty-eight, of Mr. J. W. Powell, director, since 1879, of the United States Bureau of Ethnology, and from 1880 to 1894 director of the United States Geological Survey. Mr. Powell's death occurred on September 23.

THE death, at the age of eighty-six, is reported of M. Vincent Leche Chesnevieux, the French traveller and geologist; also of Signor Adolfo Targioni-Tozzetti, emeritus professor of comparative anatomy and the zoology of the invertebrates in the Medical School at Florence. Prof. Targioni-Tozzetti was in his eightieth year.

THE *Pioneer* (Allahabad) learns from its correspondent at Kashgar that a severe earthquake occurred at that place at 8 a.m. on August 22, resulting in the loss of 1000 lives and great damage to property. A pronounced rise in the temperature immediately followed the shock. This rise continued for a week, during which period there were repeated slight shocks A Reuter telegram from Simla, dated September 26, gives the number of people killed as 667, and states that more than 1000 persons were injured.

REUTER'S agent at Mobile, telegraphing on September 30, states that information has been received by steamer that an earthquake of a serious character occurred in Guatemala and British Honduras on September 23. The shocks occurred simultaneously along the coast and lasted three minutes. It is believed that Guatemala City was the centre of the disturbances. The telegraph wires are down between Guatemala City and the coast.

A REUTER telegram from New York, dated September 24, states that the *New York Herald* has published the following telegram from Lima:—"Mount Chullapata, which is situated 18 miles from Celendin, has been throwing up dust and smoke for a fortnight. Loud noises have been audible at a distance of 30 miles from the mountain. There is no record that Mount Chullapata was ever believed to be a volcano."

A SEVERE cyclone visited the eastern Sicilian coast on Friday last from Taormina to Catania, and resulted in a heavy loss of life and very great damage to property. At Modica, two mountain torrents burst their banks and submerged the lower portion of the town as high as the second floor of the houses. The disaster was at first attributed to a waterspout, but subsequent accounts declared that it was due to torrential rains following on the prolonged drought. Throughout the day, Mount Etna sent up a thick column of steam from the vicinity of the scene of the eruption of 1892.

A SEVERE typhoon occurred at Yokohama on September 29, and a great wave broke over the adjacent district of Odawara, causing, it is feared, the loss of 200 lives; much shipping was also damaged.

AN Institute of Colonial Medicine has, says the *British Medical Journal*, recently been established in Paris. The scheme of instruction comprises courses on bacteriological and hæmatological technique, parasitology, tropical surgery, tropical ophthalmology, tropical pathology and hygiene, and tropical skin diseases. The Institute is open to foreign as well as to French medical practitioners.

THE official programme of the fourteenth International Medical Congress, to be held at Madrid from April 23 to April 30 next, has now been issued. The congress will be divided into the following sections:—Anatomy (including anthropology, comparative anatomy, embryology, descriptive anatomy, normal histology and teratology), physiology, general pathology, therapeutics, pathology, nervous diseases, children's diseases, dermatology and syphilis, general surgery, ophthalmology, oto-rhino-laryngology, obstetrics and gynæcology, military-naval medicine and hygiene, hygiene and epidemiology, and forensic medicine and toxicology.

AT the annual meeting of the Indian Association for the Cultivation of Science, held in Calcutta last month, it was decided to found a medal, to be known as the Temple medal, to perpetuate the memory of the late Sir Richard Temple for the invaluable services he rendered in the establishment of the Association.

A COURSE of four lectures is to be given at Gresham College, Basinghall Street, by Dr. E. Symes Thompson on "Food." The lectures will be delivered on October 7, 8, 9 and 10 at 6 o'clock; no charge is made for admission.

IN connection with the Universal Exposition which is to take place at St. Louis, Mo., U.S.A., in 1904, there is to be an aëronautical competition and exhibition, the rules and regulations governing which have just reached us. From them we learn that the sum of one hundred thousand dollars is offered as a grand prize, and that fifty thousand dollars are to be appropriated for minor and subsidiary prizes for competition between airships, balloons, air-ship motors, kites, &c. Information concerning the competitions is obtainable from the Chief of the Department of Transportation Exhibits, Louisiana Purchase Exposition, St. Louis, Mo., U.S.A.

ACCORDING to the *American Electrician*, a commission was recently appcinted by the New York State Legislature for the purpose of determining the advisability of establishing a State electrical laboratory to provide independent authoritative information on questions of electrical science and official standardisation of electrical measuring instruments, apparatus and standards. The commission is to report to the Legislature at the opening of its session in 1903, and if in its judgment the establishment of a laboratory is necessary, detailed plans and specifications for the construction and equipment of such a laboratory are to be prepared and submitted in connection with the commission's report.

ACCORDING to the Berlin correspondent of the *Times*, the German Government is afraid that the policy pursued by the Marconi Company, and the arrangements concluded between it and Lloyds, threaten an absolute monopoly which would be objectionable for both commercial and political reasons. Germany has therefore invited England, France, Russia, Italy, Austria-Hungary and the United States to make arrangements for a meeting of delegates to prepare a programme for an international conference to consider the subject. It is said that this suggestion has been favourably received by the States addressed, and that, as soon as a programme has been arranged, the co-operation of all maritime States will be sought in drawing up an international convention to settle the conditions under which the establishment of stations for wireless telegraphy shall be allowed. The *Electrician* suggests that the conference should take place at the International Telegraphic Conference to be held in London next year. It is to be hoped that the conference will be held soon and will be successful. We have already pointed out in these columns the growing necessity for some consolidation of the competing systems.

A NOVEL table, designed by Prof. E. C. Pickering, has been placed in the north building of the Harvard College Observatory. It is in two revolving sections, and takes the place of six separate tables which have hitherto been in use. In the upper section of the table, the annals of the observatory, magnifying glasses and reference books are kept, and the lower section is used for the storing of letters and files.

ACCORDING to the *Aeronautical World*, a new American periodical, Prof. Graham Bell has nearly oompleted his flying machine. It is being constructed under Prof. Bell's personal supervision, and is stated to be radically different from M. Santos-Dumont's machine. The machine will, it is reported, be 20 feet in length and composed of twenty-five distinct parts, and the principle of the kite will be utilised to a considerable extent.

THE *Athenaeum* learns that steps are being taken by the Department of Prisons, New South Wales, to establish a new system of criminal identification on the lines of the combined Bertillon and Francis Galton methods, modified to suit local conditions. A comprehensive criminal register is now in course of compilation, and already the anthropometrical measurements of a large number of prisoners have been taken, together with finger impressions and other distinguishing records. The work has been entrusted to Mr. M'Cauley, Deputy Controller and Inspector of Prisons, who has recently personally investigated the systems of identification pursued in the prisons of France and of the United Kingdom.

WRITING from Yokohama on August 24, Captain H. J. Snow says:—"I have never known such a cool summer since 1869. Constant rain has been the rule in this part of the country, and I think it has been similar all over Japan. Floods everywhere. The neighbourhood of the Philippines has sent us along a string of storms of small area, not one of which has come along the Pacific side of Japan. They have all either gone through the Korean Straits or across the south-western part of Japan and the Japan Sea. They have followed each other so often that the whole weather of the country has been kept in an unsettled state. Winds from north to east have prevailed nearly all the summer so far. We certainly have not had six days of southerly winds all told. The thermometer has ranged between 62° and 75° F. nearly all the time. On four or five days only it reached 84° to 86°."

THE eruption of Mont Pelée appears to have been heard as far away as Maracaibo, Venezuela, a distance of about 830 miles. In a report abstracted in the last number of the *Monthly Weather Review*, Mr. E. H. Plumacher, United States Consul at Maracaibo, writes:—"On the morning of the great calamity that has fallen upon the island of Martinique, strong rumbling sounds were heard here, as well as in the other parts of this State. At many places during the day before the catastrophe, noises of heavy cannonading were heard at La Ceiba, Cabimas, Perija and Quisiro. At Sinamaica the people thought that a great battle with heavy artillery was in progress near Maracaibo. . . . Early in the morning of the catastrophe, I found that my servant had saddled my horse; when I asked him if somebody was sick and needed a doctor, he answered that he thought I needed my horse to go to the city, as a big battle must be going on, judging from the sounds of the heavy firing of guns. Observing the same sounds, I knew at once that it could not be heavy artillery, for if all of the cannons of Venezuela were fired together, they could not produce such sounds. It was not like cannonading with heavy siege guns; it was neither thunder nor the strange, unpleasant subterranean sounds of convulsions of the earth; it was as if immense explosives were fired high up in the clouds. . . . Last night

(May 12) after eleven o'clock we had a slight horizontal trembling movement from a south-westerly direction."

AN aerial luggage transmitter has been erected recently by the L. and S.W. Railway Company at their junction at Woking, and is, we understand, in the nature of an experiment, being, it is believed, the first appliance of its kind used by any railway company in the kingdom. In briefly describing it, *Engineering* states that on the up and down platforms are erected iron towers, each 32 feet 6 inches in height, and set in blocks of concrete. Suspended from tower to tower are four spans of wire cable. The topmost cable, on which the transmitter runs to and fro, is exceptionally strong, and is capable of bearing a strain equal to at least 20 tons. The second cable keeps the transmitter in position, and the third and fourth cables, which are much thinner and are in one length, are for "paying out" and "returning." Each span is 110 feet long, and the height of the transmitter above the railway is 22 feet 6 inches. Attached to the transmitter is an iron cage capable of holding half a ton at one time. The whole is worked by hydraulic power, the engine being on the down side. Above it is a small box in which are the levers working the apparatus. The transmitter is very rapid in its working, taking only 30 seconds to deposit 10 cwt. of luggage from one platform to the other. All the experimental trials have been, it is said, most satisfactory, and the transmitter is now ready for use.

ATTENTION has recently been called to the possibilities of the balata fields on the Amazon. A gutta-percha merchant in the Guianas, examining this region about a year ago, found the balata tree growing in abundance near Para, and on the Amazon and its tributaries for thousands of miles. The Brazilians had no knowledge of its gum-producing qualities, and were found cutting down the trees for firewood and building material. A concession was bought, and the practical work of producing gutta-percha for the market begun. As in the case of rubber, there is practically no limit to the supply of gutta-percha on the Amazon, and, as it can be produced at a fraction of the cost of rubber, it offers a much higher percentage of profit. The method of bleeding the balata tree is entirely different from that used to extract the gum of the rubber tree, and only experienced and expert bleeders can be employed. But, on the other hand, these trees yield many times as much sap as the rubber trees, and one man can, it is said, easily produce as many kilograms of gutta-percha in a day as twenty men can extract of rubber. Each tree will average 3½ lb. of gutta-percha and a competent bleeder can prepare 40 to 50 lb. per day. The gum is first fermented and then dried in the sun, after which it is ready for shipment.

WE have received several communications on the variation of the small copper butterfly (*Chrysophanus Phlaeas*, Linn.) with reference to the letter of a correspondent in our issue of September 11. The insect is very variable, and the row of blue spots inside the dark border of the hind wing, which has been specially referred to, is not uncommon, and according to Rühl ("Palæarktischen Grossschmetterlinge," i. p. 217) is only met with in the female. The insect extends throughout the whole northern hemisphere, and exhibits local variation in many parts of its range. In the south of Europe and Asia, a larger and darker variety, with rudimentary tails (var. *Eleus*, Fabricius), is not uncommon. The species is also very prone to albinism, specimens with the usual copper colour of the wings replaced by white, leaving only the black markings dark, being occasionally met with var. *Schmidtii*, Gerhard). We are not aware that it ever hybridises with "blues," as one of our correspondents has suggested. We may refer readers who require further information to the following works:—Barrett's "Lepidoptera of the British Islands," vol. i. pp. 62-65, plate 2, Figs. 2, 2*a* to 2*j* (Fig. 2*a* represents the white form); Tutt's "British Butterflies," pp. 152-155; Mosley's "Illustrations of Varieties of British Lepidoptera," part 10 ("Polyommatus Phlæas"), plates 1 and 2 (twelve varieties figured, some very remarkable, including not only coppery and black and white forms, but a dark greyish brown specimen, slightly suffused with copper and marked with a few large black spots); Rühl's "Palæarktischen Grossschmetterlinge," Band 1, pp. 217, 218, 746, 747 (this work gives full information respecting the foreign range and variation of the insect); Staudinger and Rebel, "Catalog der Lepidopteren des Palæarctischen Faunengebietes," p. 74. Mr. F. Merrifield has also called our attention to his paper on "The Coloration of *Chrysophanus Phlaeas* as affected by Temperature," in the *Entomologist* for November, 1893 (vol. xxvi. pp. 333-337).

THE report on "British Rainfall for the Year 1901," compiled by Mr. H. S. Wallis and Dr. H. R. Mill (60 + 252 pp. large 8vo), contains, as usual, most valuable and trustworthy data, showing the annual distribution of rain over the British Isles, as observed at about 3500 stations, together with the number of days on which 0·01 inch or more fell. This most useful organisation is so well known that it seems scarcely necessary to refer to the articles which regularly appear upon various branches of rainfall work. The notes on the meteorology of the year and on the principal phenomena, arranged according to months, are exceedingly interesting and valuable for reference, as are also the tables showing the heavy falls in short periods and the monthly rainfall at 232 stations. The comparison of the rainfall of the year with a thirty years' average is very instructive, and shows at a glance that, on the whole, there has been a great deficiency in the total amount. In the eastern counties the deficiency reached 30 or 35 per cent. of the normal value.

IN the *Transactions* of the South African Philosophical Society of June last, Mr. J. R. Sutton contributes an elaborate paper on the "Pressure and Temperature Results for the Great Plateau of South Africa," accompanied by useful daily and monthly means for the years 1888-97. The discussion exhibits a systematic comparison between the temperatures and pressures of the air over a plateau and corresponding coast station, as represented by observations at Kimberley and Durban, similarly to comparisons between the summit and base of a mountain.

THE United States Weather Bureau has published a valuable memoir on West Indian hurricanes (*Bulletin* No. 32), prepared by Mr. W. H. Alexander from all available sources. Part of the information has been published in a previous *Bulletin*, but the present paper includes additional observations on those of St. Kitts and Porto Rico in particular, with brief historical notes of the most remarkable storms that have occurred from the earliest times.

THE *Journal* of the College of Science of Tokio (vol. xvi. article 7) contains an interesting paper entitled "Studies in Atmospheric Electricity," by Prof. Y. Homma. The facts discussed have been obtained chiefly from observations and documents belonging to the Central Meteorological Observatory of Japan. The principal conclusions are:—(1) The negative potential observed during strong wind is entirely due to the negative electrification of the dust in the atmosphere by friction with terrestial objects; (2) similarly the high potential observed during fog or haze is due to the positive electrification of the water particles composing it; (3) when a mass of cold air comes in contact with a mass of warm air, the former becomes positively electrified with respect to the latter; (4) the high potentials about sunrise are probably owing to the air near the surface having a lower temperature than the air above it, and becoming, in consequence, positively electrified; (5) when two masses of air at different temperatures happen to be mixed suddenly, the

electric field is violently disturbed. Various types of potential are illustrated by reproductions of photographic curves of a self-recording electrometer.

It is often necessary in experimental work to maintain a condenser continuously charged at a constant high potential for a considerable length of time, and various methods, none of them altogether satisfactory, have been proposed. An "electrostatic relay" suitable for this purpose is described by M. V. Crémieu in the *Journal de Physique* for September. The form hitherto found most satisfactory depends essentially on the action of an electrostatic balance, which automatically makes or breaks contact in an electric circuit when the potential passes a certain value, thereby connecting or disconnecting the condenser to be charged and an electrostatic machine. The objection to this arrangement arises from the fact that a certain force is necessary either to make or break the contact, and hence the potential of the condenser may fluctuate as much as 22 per cent. The arrangement which M. Crémieu now proposes obviates this difficulty. In one of the contacts there is no adhesion of the terminals and no sparking, because when the contact is made only a very small quantity of electricity flows through it, and when it is broken the terminals are both at the same potential. In the only contact in which adhesion may occur, the terminals are separated by a force which can by adjustment of the apparatus be made as large as desired. It results that the present arrangement is capable of regulating the potential of a condenser of 1 kilometre capacity, charged up to 5000 volts, to within $\frac{1}{2}$ per cent.

MR. J. L. WORTMAN contributes part i. of "Studies of Eocene Mammalia in the Marsh Collection, Peabody Museum" (*Amer. Journ. Science*, ser. 4, vols. xi.–xiv., 1901–1902). In this work the Carnivora are dealt with, the ancestral relations and progressive modifications of the several families are considered, some new genera and species are described, others are freshly defined, and some, like Triacodon, Ziphacodon and Harpalodon, are not regarded as valid genera. The author also discusses the general organisation of the Carnivora and the relationship of its more primitive members to the metatherian marsupials.

IN an exhaustive memoir relative to the Mexican meteorites which was published in the *Mineralogical Magazine* in 1890 (vol. ix. pp. 91–178), Mr. Fletcher called attention to the fact that a large mass of meteoric iron, found in 1867 in an ancient grave at Casas Grandes de Malintzin, Chihuahua, Mexico, and thus of much archæological interest, had not been heard of since 1873, in which year it was said to be about to be transported from Casas Grandes to the United States consulate at El Paso. Mr. Fletcher suggested that the missing mass was possibly identical with one which had been shown in the Mexican mineral exhibit at the United States International Exhibition of 1876 and had been afterwards transferred to the Smithsonian Institution. On investigation, the Washington authorities were convinced that the suggestion was well founded. Mr. Wirt Tassin has now published (*Proceedings* of the United States National Museum, 1902, vol. xxv. p. 69) a description of the mineralogical and chemical characters of the mass. Very sharply defined Widmanstätten figures are developed by the etching of a polished face. The percentage of nickel (and cobalt) varies in different parts from 4·5 to 5·3. The chemical composition of one of the alloys (tænite) corresponds to the formula Fe_6Ni. As is usual in meteoric irons, both troilite (ferrous sulphide) and schreibersite (phosphide of iron and nickel) are present; both minerals were isolated and analysed. Cliftonite, the cubic form of graphitic carbon, was carefully sought for, but only massive graphitic carbon was found.

IN the course of an interesting paper on the crustacean fauna of the Mammoth Cave, Kentucky, and its neighbourhood, forming No. 1285 of the *Proceedings* of the U.S. Museum, Mr. W. P. Hay describes a new form of blind shrimp discovered by himself in one of the streams passing through the cave. This shrimp, which belongs to a family previously unknown from the North American Continent, is referred to a new genus, although it appears to come very close to Xiphocaris, of which one representative is found in the West Indies, a second in New Zealand and a third in the Indo-Malay region. The author is of opinion that the group is a very ancient one and that the cave-forms have survived in districts whence their relatives have migrated south.

THE Report of the Director of the Botanical Survey for the year 1901–1902 has been received, and includes the independent reports of the directors of the three botanical departments. The chief items of interest are the failure of attempts to introduce the plant *Paspalum dilatatum*, which has a considerable reputation in America and Australia as a drought-resisting fodder grass, hybridisation experiments with wheat, and various sugar-cane pests and diseases.

WE have received a subject list of works on domestic economy, foods and beverages, including the culture of cacao, coffee, barley, hops, sugar, tea and the grape, in the library of the Patent Office. The list comprises 1270 works.

THE September issue of the *Agricultural Journal* of the Cape of Good Hope contains a powerful plea for the use of the metric system in South Africa from the pen of Mr. D. E. Hutchins, conservator of forests, western districts of Cape Colony. The number also contains the communications on the "Misuse of Coal" by Prof. John Perry, F.R.S., and Mr. Hutchins which appeared in our columns on March 20 and July 10 respectively.

THE same number of the journal has a note upon some French experiments which have been made respecting the use of salt in the dietary of sheep. Three lots of sheep were fed identically, excepting that one lot had no salt, another lot had half an ounce every day and the remainder three-quarters of an ounce daily. Those receiving half an ounce gained 4·5 pounds each more than those which had no salt and 1·25 pounds more than those which had more than half an ounce. The salted sheep had 1·75 pounds more wool and a better fleece than those which had no salt.

THE current issue of *Engineering* contains a description of the proposed scheme for the transmission of letters, newspapers and parcels by an aërial electric railway which is at present under the consideration of the Italian Minister of Posts and Telegraphs, to which we briefly referred in our columns of September 18.

THE *Times* of Thursday last contains an interesting account, by Mr. J. Y. Buchanan, F.R.S., of the recently completed fourth annual scientific cruise of the Prince of Monaco's steam yacht *Princesse Alice*.

A NEW edition, the sixth, of Lord Avebury's "The Origin of Civilisation and the Primitive Condition of Man" has just been issued by Messrs. Longmans and Co. The author, in his preface, states that he sees no reason to change in any essential respects the opinions originally expressed by him in the first edition of the book thirty years ago. The present issue of the work contains, however, numerous additions here and there.

THE Report of the proceedings and abstracts of the papers read at the International Engineering Congress held in Glasgow in 1901 has been issued in volume form by Mr. W. Asher, of Glasgow.

MESSRS. Philip Harris and Co., Ltd., Birmingham, have sent us a handy little pocket diary giving, besides space for notes, addresses, &c., particulars and dates of the various science examinations which are to take place during the session 1902-3.

THREE catalogues which should be of interest to our readers have reached us, viz., a "Subject List of Works on the Textile Industries and Wearing Apparel, including the Culture and Chemical Technology of Textile Fibres, in the Library of the Patent Office" (issued by the Patent Office); "Catalogue of Geological Books and Papers," on sale by Dulau and Co.; and a "Catalogue of Miscellaneous Books in Literature, Science and Art," offered by Sotheran and Co.

THE additions to the Zoological Society's Gardens during the past week include a White-throated Capuchin (*Cebus hypoleucus*) from Central America, presented by Dr. O. Inchley; an African Civet Cat (*Viverra civetta*) from Sierra Leone, presented by Mr. Reginald Espeut; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. Alfred Stockman; a Sparrow Hawk (*Accipiter nisus*), British, presented by Mr. M. T. England; a Nilotic Crocodile (*Crocodilus niloticus*) from Africa, presented by Mr. L. C. Ditton; a Common Boa (*Boa constrictor*) from Trinidad, presented by Mr. W. J. Sanger Tucker; a Macaque Monkey (*Macacus cynomolgus*) from India, a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, four Lesser Egyptian Gerbilles (*Gerbillus aegyptius*) from North Africa, a Great Anteater (*Myrmecophaga jubata*) from South America, a Spix's Macaw (*Cyanopsittacus spixi*), ten Cope's Terrapins (*Hydromedusa tectifera*) from Brazil, a Limbless Lizard (*Pygopus lepidopus*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

EPHEMERIS FOR THE SEARCH OF THE COMET TEMPEL$_3$-SWIFT.—M. F. Bossert contributes to No. 3811 of the *Astronomische Nachrichten* an ephemeris for the search for this comet. An extract is given herewith :—

12h. Paris M.T.

1902.	α h. m. s.	δ ° ′	log *r*.	log Δ.
Oct. 1	19 3 28	−19 12·2	0·2518	0·1335
,, 6	8 1	18 58·1	0·2421	0·1385

,, 31	43 54	17 12·0	0·1909	0·1563
Nov. 5	19 53 28	−16 41·3	0·1803	0·1582

GRIGG'S COMET.—The comet which was announced by Mr. John Grigg has been named 1902 *c*, and the following ephemeris has been calculated for it by Herr M. Ebell, taking T = June 20·0 Berlin M.T., from the elements previously published :—

1902.	α h. m.	δ ° ′	log *r*.	log Δ.	Brightness.
May 20	4 13·7	+16 15	9·9407	0·2706	0·38

Sept. 25	15 57·5	− 8 22	0·2855	0·3536	0·05
Oct. 27	17 4·0	−10 39	0·3785	0·4773	0·02

Unit of brightness on July 23. (*Astronomische Nachrichten*, 3816.)

REAPPEARANCE OF EROS.—This planet was visually rediscovered by Dr. Charles J. Ling, using the 20-inch refractor of the Chamberlain Observatory, at 3.15 a.m. on August 2. On August 7, Dr. Ling made an accurate determination of the planet's position and magnitude, and this showed the right ascension to be 15 seconds less than the computed R.A. obtained from Miss M. C. Traylor's ephemeris; the declination only shows a variation of less than 1 minute from the position given by the ephemeris. Dr. Ling estimated the magnitude to be 1m.·0 brighter than one would expect from the observations published in No. 61 of the Harvard College *Circular*, and he has confirmed his estimate on several later occasions. As these estimations were made when the planet was low down in the east and just before dawn, it is not likely that he has over-estimated the brightness; photometric measures should therefore be made as soon as possible by those observatories which are equipped for this work.

Eros is now moving eastward nearly as fast as the sun, and will move southwards for several months, so that it will not be very favourably situated for observers in the northern hemisphere. Its position on August 11 at 15h. 25m. 19s. (University Park M.T.) was :—

R.A. 5h. 36m. 35s.·03
Dec. + 31° 56′ 17″·7
(*Popular Astronomy*, No. 97.)

A REMARKABLE METEOR.—A meteor of extraordinary brightness was observed at Earlsfield, Surrey, on the evening of September 29.

Two observers, Mr. Archibald McDougall, of Earlsfield, and Mr. W. E. Rolston, of the Solar Physics Observatory, were, at the moment of the meteor's appearance, looking at that part of the sky in which it was first visible, and both were very much surprised by the brightness and beauty of the appearance. They recorded the following data regarding the phenomenon :—

At 10.16 p.m. the meteor appeared as a faint greenish trailing light, having a phosphorescent appearance, in the S.S.W., and very deliberately travelled in a south-eastern direction. Its altitude at the commencement of its flight was about 25° to 30°, and its bursting point was 10° to 15° above the horizon. The head gradually swelled out into an elongated pear-shaped mass, and the light emitted by it on bursting was of a yellowish red tinge, which afterwards became rose-coloured. The whole phenomenon occupied about 4 to 5 seconds, but the faint greenish trail disappeared, closing up from its starting point, in about 1½ seconds; this trail was about 10° long. The meteor was appreciably brighter than Jupiter; it first appeared about halfway between α and γ Aquarii and then travelled in the direction of Cetus.

Several other bright meteors were seen by Mr. Rolston on the same evening.

METEOR RADIANTS.—In a list of radiants observed at the Observatory of Athens during 1900 and 1901, M. Eginitis records in the *Astronomische Nachrichten* (No. 3815) two new radiants, and three which he says are "probably new."

During 1900 and 1901, the maximum of the Perseid shower was recorded as occurring on August 11, the principal radiant being situated near to η Persei, whilst the principal point from which the Leonids seemed to radiate was recorded as being situated near to Regulus. M. Eginitis remarks on the number of different radiants from which each shower appears to proceed.

INSTRUCTIONS ON THE OBSERVATION OF THE SUN.—Under this heading, "La Commission Solaire" publish, in the September *Bulletin de la Société Astronomique de France*, an introduction to the "Instructions for Solar Observations," of which they propose to send a copy to all members of the Société Astronomique who intend taking part in the solar observations the preparation and collection of which form the *raison d'être* of the commission recently appointed.

The introduction first points out the vital importance of an earnest and continuous study of solar physics, and then proceeds to state under twenty-one subheadings the details of these studies, the necessity for each, and the necessity for the continuous gathering together and the reduction of the whole work. M. Deslandres, who is the writer of the introduction, especially insists upon the absolute necessity of the co-operation of many observers in this work.

CORRECTIONS TO THE RIGHT ASCENSIONS OF THE PRINCIPAL STARS OF THE BERLINER JAHRBUCH.—Nos. 3813 and 3814 of the *Astronomische Nachrichten* are devoted to an account, by Senor Campos Rodrigues, of the methods pursued, and the results obtained thereby, in determining the corrections obtained at Lisbon to the right ascensions of 384 of the principal stars given in the Berliner Jahrbuch.

Senor Rodrigues describes the meridian circle and the instrumental aids which he has used in this work, and then sets out in tabular form the results he has obtained since he commenced the work in 1887.

OBSERVATIONS OF PERRINE'S COMET, 1902 *b*.

THIS comet was discovered by Perrine, using the 12-inch refractor of the Lick Observatory, on the morning of September 1, and the discovery was published by the following telegram, of that date, from Prof. Pickering to the Kiel Centralstelle:—"A comet was discovered by Perrine August 31, 16h. 8m. 16s. Lick, α app. 3h. 17m. 49s.·4, δ app. + 34° 38′ 47″, slightly elongated, mean diameter 4′, magnitude 9, tolerably well-defined nucleus, tail." This object was also discovered, independently of Perrine, by M. Borelly, of the Marseilles Observatory, on September 2, 9h. 50m.·4, and the observation was forwarded to Kiel in a telegram from M. Lœwy, which stated that the comet's position, at the time of its discovery, was α = 49° 9′, N.P.D. = 54° 48′, its daily movement − 15′ and − 26′ respectively, and that it possessed a nucleus and a tail.

Further observations were made by Perrine, and the following parabolic elements, ephemeris and details have been obtained therefrom:—

Elements of Comet 1902 *b*.

T = 1902 November 23·472 G.M.T.

$$\begin{aligned} \omega &= 153^\circ\ 25'\ 46'' \\ \Omega &= 49\ \ 56\ \ 10 \\ i &= 156\ \ 54\ \ 22 \\ \log q &= 9{\cdot}60424. \end{aligned}$$

Ephemeris for 12*h*. *G.M.T.* (*Perrine*).

1902.	True α. h. m. s.	True δ. ° ′	log. Δ.	Brightness.
Oct. 5·5	20 55 49	+50 28	9·566	27·1
22·5	17 43 15	+ 3 53	9·812	16·1
Nov. 8·5	16 57 23	−11 0	0·040	13·9
23·5	16 13 8	−18 13	0·139	17·2

The brightness given for each day is the value obtained on comparison with the brightness at the time of discovery, calling the latter unity. Perrine adds that, when discovered, the comet had a magnitude of 9, with a well-defined, but not stellar, nucleus of magnitude 10·5 or 11·0; the diameter of the coma was 4′ to 5′, whilst the short, brushy tail could be traced to the south-west for a distance of 8′ to 10′. As a correction to the telegram dispatched to the various observatories on September 2, he mentions that the calculated time of perihelion passage is November 23·47, and not November 24·47 as was stated in that telegram.

The above elements and ephemeris agree fairly closely with those calculated by Herr Elis Strömgren, of Kiel, from observations made at Lick (September 1·05), Urania (September 2·58) and Copenhagen (September 4·61), and he has calculated an ephemeris for every day from September 6 to October 16. Part of this ephemeris is given below, and from it has been prepared the accompanying chart, which shows the comet's approximate daily positions with regard to the neighbouring stars.

Ephemeris for 12*h*. *M.T.* (*Berlin*). (*Strömgren*.)

1902.	α app. h. m. s.	δ app ° ′	Brightness.[1]

13	34 31	23 2·3	
14	25 42	20 6·2	
15	17 54	17 23·3	
16	18 10 58	14 53·3	21·8

[1] Brightness at time of discovery = 1.

MM. Borelly and Fabry, of the Marseilles Observatory, have observed the comet on several occasions since its discovery by the former, and they report that it is fairly brilliant, has an elongated nucleus and a tail 10′ to 12′ long. On September 2, at 14h. (Marseilles M.T.), the nucleus appeared to become double and thus form two small, globular nuclei; on September 3 it had much the same aspect, but on September 5 the nucleus was more diffuse and the light of the comet appeared to sensibly diminish.

It may be seen from the above ephemerides that the comet will attain its maximum brightness about October 8 and that it

FIG. 1.

passed its maximum declination on September 30, so that by November 30 it will be comparatively faint, and so far south that it will be a difficult object for observers in the northern hemisphere, except on very fine nights and in clear atmospheres; at present (September 27) it is an easy object to find with an ordinary opera-glass, and, given good meteorological conditions, it should soon become obviously visible to the naked eye.

FORTHCOMING BOOKS OF SCIENCE.

THE announcements of Messrs. Baillière, Tindall and Cox contain:—"Manual of Operative Surgery," by H. W. Allingham; "Manual of Medicine for Students and Practitioners," by Dr. T. K. Monro; "Refraction of the Eye," by E. Clarke; "Drugs: their Production, Preparation and Properties," by H. W. Gadd; "Anæsthetics," by Dr. J. Blumfeld; "Aids to the Analysis and Assay of Metals, Ores and Fuels," by J. J. Morgan; "Suggested Standards of Purity for Food and Drugs," by C. G. Moor; "Selected Papers on Operative Surgery," by Sir William Stokes; "The Dental Annual, and Year-Book of Dental Surgery"; "Artistic Poses," by Dr. R. Colenso, illustrated; "The Common Colics of the Horse," by T. C. Reeks; "Pulmonary Consumption," by Dr. A. C. Latham (winner of the King's prize of 500*l*.); and new editions of Politzer's "Text-Book of the Diseases of the Ear and Adjacent Organs," translated by Drs. C. L. Heller and M. J. Ballin; Cross and Cole's "Modern Microscopy"; Fleming's "Veterinary Surgery," edited by Prof. Macqueen, vol. i.; Allan's "Aids to Sanitary Science"; Rose and Carler's "Manual of Surgery"; Gresswell's "Veterinary Pharmacopœia"; Courtenay's "Veterinary Medicine," edited by Prof. Hobday; Murrell's "Aids to Forensic Medicine and Toxicology"; Gubb's "Aids to Gynæcology."

Messrs. A. and C. Black give notice of:—"Problems in Astrophysics," by Agnes M. Clerke, illustrated; "Descriptive Geographies from Original Sources," edited by Dr. A. J. Herbertson and F. D. Herbertson:—Africa, Asia and Europe, illustrated; "Geography Readers," by L. W. Lyde:—British Empire, illustrated; Africa.

Messrs. Blackie and Son, Ltd., promise "The Coal-Fields of Scotland," by Robert W. Dron.

Messrs. Wm. Blackwood and Sons announce:—"An Introductory Text-Book of Logic," by Dr. S. H. Mellone; "The Psychology of Ethics," by Prof. D. Irons.

The announcements of the Cambridge University Press include:—"The Geography of Disease," by Dr. Frank G. Clemow; "A Treatise on Spherical Astronomy," by Prof. Sir Robert S. Ball, F.R.S.; "Dr. William Turner's Treatise 'De Avibus,' Cologne, 1544, translated and edited by A. H. Evans; "The Fauna and Geography of the Maldive and Laccadive Archipelagoes: being the Account of the Work carried on and of the Collections made by an Expedition during the years 1899 and 1900 under the Leadership of J. Stanley Gardiner," vol. i. part

iii., illustrated; "The Algebra of Invariants," by J. H. Grace and A. Young; "Reports of the Anthropological Expedition to Torres Straits by the Members of the Expedition," edited by Dr. A. C. Haddon, F.R.S.; "Solutions of the Examples in the Elements of Hydrostatics," by S. L. Loney; "Immunity in Infectious Diseases," by Prof. Élie Metchnikoff, authorised English translation by F. G. Binnie, illustrated; "Scientific Papers," by John William Strutt, Baron Rayleigh, F.R.S., vol. iv.; "The Principles of Mathematics," vol. i., by Bertrand Russell; "The Sub-mechanics of the Universe," by Prof. Osborne Reynolds, F.R.S.; "On an Inversion of Ideas as to the Structure of the Universe: being the Rede Lecture for 1902," by Prof. O. Reynolds, F.R.S.; "A Treatise on Determinants," by R. F. Scott, F.R.S., a new edition by G. B. Mathews, F.R.S.; "Index Nominum Animalium," compiled by C. Davies Sherborn, under the supervision of a committee appointed by the British Association and with the support of the British Association, the Royal Society and the Zoological Society, vol. i. (1758–1800); "The Electrical Properties of Gases," by Prof. J. J. Thomson, F.R.S.; "A Course of Modern Analysis: an Introduction to the General Theory of Infinite Series and of Analytic Functions, with an Account of the principal Transcendental Functions," by E. T. Whittaker; "A Sytematic Account of the Seed-Plants," by Dr. A. B. Rendle, vol. i.:—Introduction, Gymnosperms, Monocotyledons; "Fossil Plants: a Manual for Students of Botany and Geology," by A. C. Seward, F.R.S., vol. ii.; "A Primer of Botany," by F. F. Blackman; "A Primer of Geology," by J. E. Marr, F.R.S.; "A Brief History of Geographical Discovery since 1400," by Dr. F. H. H. Guillemard; "An Introduction to Physiography," by Dr. W. N. Shaw, F.R.S.; and a new edition of "Solution and Electrolysis," by W. C. D. Whetham.

Messrs. Cassell and Co., Ltd., promise:—"The Dominion of the Air: the Story of Aërial Navigation," by the Rev. J. M. Bacon, illustrated; "White's Natural History of Selborne," with notes by R. Kearton, illustrated.

Messrs. W. and R. Chambers, Ltd., will issue a new edition of "Organic Chemistry," by Profs. W. H. Perkin, jun., F.R.S., and F. Stanley Kipping, F.R.S., part i.

Messrs. J. and A. Churchill announce:—"A Manual of Hygiene," by Dr. Hamer; "Pathological Anatomy and Histology," by Dr. Lazarus-Barlow; "A Handbook of Clinical Medicine," by Dr. T. D. Savill; "Cancer of the Stomach," by Dr. Fenwick and Dr. W. Soltau Fenwick; "Obstinate Hiccough," by Dr. Knuthsen; "Electric Lighting," edited by W. J. Dibdin (being the fourth volume of Groves and Thorp's "Chemical Technology"); and new editions of Morris's "Treatise on Anatomy"; Starling's "Elements of Human Physiology"; Heath's "Practical Anatomy," revised by J. Ernest Lane; Coles's "The Blood"; Haig's "Diet and Food"; Bloxam's "Chemistry: Inorganic and Organic."

Messrs. T. and T. Clark promise:—"The Religion of the Ancient Egyptians and Babylonians, being the Gifford Lectures on the Conception of the Divine in Egypt and Babylonia," by Prof. A. H. Sayce; "Explorations in Bible Lands during the Nineteenth Century," edited by Prof. Herman V. Hilprecht; "Euclid, his Life and System," by Dr. T. Smith; "Hegel and Hegelianism," by Prof. R. Mackintosh.

Mr. W. B. Clive gives notice of:—"Matriculation Advanced Algebra and Geometry," edited by Dr. Wm. Briggs; "The New Matriculation Chemistry, being the 'Tutorial Chemistry,' Part I., with Matriculation Supplements on Metals and their Compounds and the Chemistry of Daily Life," by Dr. G. H. Bailey; "The New Matriculation Botany," by Dr. A. J. Ewart; "Matriculation Geography, Physical and General, both for the London Matriculation Examination (Revised Regulation)"; "Practical Plane and Solid Geometry, First Stage," by G. F. Burn: "Applied Mechanics, First Stage"; "Organic Chemistry (Theoretical), First Stage," by R. A. Lyster; "Mining, First Stage"; "Steam, First Stage"; "Advanced Hygiene," by Alfred E. Ikin and Robert A. Lyster.

Messrs. Archibald Constable and Co., Ltd., call attention to:—"The Prevention of Disease, Prophylaxis in Surgery Operations, the Treatment of Fractures and Dislocation, Wounds, Deformities and Tumours, Medicine and Insanity," translated from the German, edited with introduction by H. Timbrell Bulstrode; An English Garner:—Geographical: iv.–v., "Voyages and Travels, mainly of the Seventeenth Century," edited by C. Raymond Beazley.

Messrs. R. A. Everett announce:—"The Horse, from Birth to Old Age," by S. Buckman-Linard, illustrated; "Age and Old Age: a Handbook on Health and Disease," by Dr. David Walsh.

The following are among the announcements of Messrs. Charles Griffin and Co., Ltd.:—"Physico-chemical Tables for the Use of Analysts, Physicists, Chemical Manufacturers and Scientific Chemists," by John Castell-Evans, vol. ii.:—Chemical Physics, Pure and Analytical Chemistry; "Electrical Engineering in Colliery Practice," by D. Burns, illustrated; "The Metallurgy of Steel," by F. W. Harbord, illustrated; "The Elements of Metallurgical Chemistry: an Introduction to Chemistry for Students of Science Classes," by John H. Stansbie, illustrated; "Emery Grinding Machines: a Text-Book of Workshop Practice in General Tool Grinding, and the Design, Construction and Application of the Machines Employed," by R. B. Hodgson, illustrated; "Modern Electric Tramway Traction: a Text-Book of Present-Day Practice for the Use of Electrical Engineering Students and those interested in Electric Transmission of Power," by Prof. Andrew Jamieson, illustrated; "Open-Air Studies in Bird-Life: Sketches of British Birds in their Haunts," by Charles Dixon, illustrated; "Official Year-Book of Scientific and Learned Societies of Great Britain and Ireland," nineteenth annual issue; "The Chemistry of India Rubber: a Treatise on the Nature of India Rubber, its Chemical and Physical Examination, and the Determination and Valuation of India Rubber Substitutes, including the Outlines of a Theory on Vulcanisation," by Dr. Carl Otto Weber, illustrated; "Technical Mycology: the Utilisation of Micro-Organisms in the Arts and Manufactures, a Practical Handbook on Fermentation and Fermentative Processes for the Use of Brewers and Distillers, Analysts, Technical and Agricultural Chemists, and all interested in the Industries dependent on Fermentation," by Prof. Franz Lafar, translated by Charles T. C. Salter, vol. ii. part i., illustrated; "The Work of the Digestive Glands," by Prof. Pawlow, translated by Prof. W. H. Thompson (the Nobel prize researches in physiology, 1901, sole authorised edition for England and America); "Hygiene and Public Health," by Dr. H. W. G. Macleod, illustrated.

Mr. Heinemann promises:—"Mutual Aid, a Factor of Evolution," by Prince Kropotkin; "The Care of the Teeth," by Dr. Samuel A. Hopkins; "The Regions of the World," edited by H. J. Mackinder, vol. iii., "Central Europe," by Dr. Joseph Partsch; "Through the Heart of Patagonia," by Hesketh Prichard, illustrated.

Mr. H. K. Lewis announces:—"Handbook of the Pathology of the Skin, being an Introduction to the Histology, Pathology and Bacteriology of the Skin, with special reference to Technique," by J. M. H. MacLeod, and new editions of "Diseases of the Skin, their Description, Pathology, Diagnosis and Treatment," by H. Radcliffe-Crocker; "Hygiene and Public Health," by Drs. Louis C. Parkes and H. R. Kenwood; "Ophthalmic Practice," by Charles Higgens, revised with the assistance of A. W. Ormond.

Messrs. Crosby Lockwood and Son announce:—"Surveying as practised by Civil Engineers and Surveyors," by John Whitelaw, jun.; "Electricity as applied to Mining," by Arnold Lupton, G. D. Aspinall Parr and Herbert Perkin; "A Short Text-Book of Oil Analysis," by A. C. Wright; "The Care and Management of Stationary Steam Engines," by Charles Hurst; "The Electro-Plating and Electro-Refining of Metals," being a new edition of Alex. Watts's "Electro-Deposition," rewritten by Arnold Philip; and new editions of E. H. Davies's "Machinery for Metalliferous Mines"; "Factory Accounts," by E. Garcke and J. M. Fells; "The Cyanide Process of Gold Extraction," by M. Eissler; Clement Mackrow's "Naval Architect's and Shipbuilder's Pocket-Book"; A. C. Wannan's "Marine Engineer's Guide."

Messrs. Longmans and Co.'s list includes:—"The Practitioner's Guide," by Dr. J. Walter Carr, T. Pickering Pick, Alban H. G. Doran and Dr. Andrew Duncan, illustrated; "An Introduction to Bacteriology" (specially designed for Indian medical students), by Dr. M. L. Dhingra; "Fermentation Organisms," by Dr. Klöcker, translated by G. E. Allan and J. H. Millar; "Bacteria in Daily Life," by Mrs. Percy Frankland; "The Great Mountains and Forests of South America," by Paul Fountain, illustrated; "Light Railway Construction," by Richard Marion Parkinson, illustrated; "The Teaching of Chemistry and Physics in the Secondary School," by Profs. Alexander Smith and Edwin H. Hall, illustrated; "Biology

(Nature Study, Botany and Zoology)," by Prof. Francis E. Lloyd and Maurice A. Bigelow; "The Mycology of the Mouth: a Text-Book of Oral Bacteria," by Kenneth W. Goadby, illustrated; "Mechanics: Theoretical, Applied and Experimental," by W. W. F. Pullen, illustrated; "Elementary Biology, Descriptive and Experimental," by John Thornton, illustrated; "British Museum Publications: a Guide to the Antiquities of the Stone Age in the Department of British and Mediæval Antiquities," illustrated; "The Beginnings of Trigonometry: for Use on the Modern Side of Schools," by Dr. A. Clement Jones; and a new edition of "Materia Medica, Pharmacology and Therapeutics: Inorganic Substances," by Dr. Charles D. F. Phillips.

Messrs. Sampson Low and Co., Ltd., announce:—"A Manual of Indian Timbers: an Account of the Growth, Distribution and Uses of Indian Trees and Shrubs, with Descriptions of their Wood Structure," by J. S. Gamble, F.R.S., illustrated; "Modern Workshop Hints," by R. Grimshaw, illustrated; "Thallner's Tool-Steel: a concise Handbook on Tool-Steel in General," translated from the German by W. T. Brannt, illustrated.

In the announcements of Messrs. Macmillan and Co., Ltd., we notice:—"Across Coveted Lands: or, a Journey from Flushing to Calcutta Overland," by A. H. Savage Landor, 2 vols., illustrated; "Tribes of the Malay Peninsula," by W. W. Skeat, illustrated; "Life in Mind and Conduct: Studies of Organic in Human Nature," by Dr. Henry Maudsley; "What is Meaning?" by Victoria, Lady Welby; "Mineralogy, an Introduction to the Scientific Study of Minerals," by Prof. Henry A. Miers, F.R.S., illustrated; "Text-Book of Palæontology," by Prof. Karl A. von Zittel, translated and edited by Dr. Charles R. Eastman, English edition revised and enlarged by the author and editor and others, vol. ii., illustrated; "A Manual of Medicine," edited by Dr. W. H. Allchin, vol. iv.:—Diseases of the Respiratory System and of the Circulatory System; vol. v.:—Diseases of the Digestive System and of the Kidneys; "Wild Fowl," by Leonard C. Sanford and T. S. Van Dyke, illustrated; "Big Game Fish," by Charles F. Holder, illustrated; "Gun and Rifle," by A. W. Money, W. E. Carlin and A. L. A. Himmelweight, illustrated; "First Lessons in Agriculture," by Prof. L. H. Bailey; "The Principles of Stock Breeding: the Application of Biological Laws to the Breeding of Domestic Animals (including Poultry), whether for Fancy or Profit," by Prof. W. H. Brewer; "The Care of Stock," by Prof. N. S. Mayo; "An Introduction to Celestial Mechanics," by Dr. F. Ray Moulton, illustrated; "Climatology," by Prof. Julius Hann, translated by R. De Courcy Ward; "The Diamond Mines of South Africa: some Account of their Rise and Development," by Gardner F. Williams, illustrated; "Outlines of Psychology," by Prof. J. Royce; "Dictionary of Philosophy and Psychology," edited by Prof. J. Mark Baldwin, vols. ii. and iii.; "Experimental Psychology: a Manual of Elementary Laboratory Practice," by Prof. E. B. Titchener, vol. ii.:—Quantitative Experiments; and new editions of "A Text-Book of Geology," by Sir Archibald Geikie, F.R.S., illustrated; "A Text Book of Botany," by Dr. E. Strasburger and others, translated by Dr. H. C. Porter, revised by Dr. W. Lang; "Elementary Applied Mechanics," by Profs. T. Alexander and A. W. Thomson.

Mr. John Murray gives notice of:—"Volcanic Studies," by Dr. Tempest Anderson, illustrated; "In the Andamans and Nicobars: the Narrative of a Cruise in the schooner *Terrapin*, with Notices of the Islands, their Fauna, Ethnology, &c.," by C. Boden Kloss, illustrated; "A Naturalist in Indian Seas, or Four Years with the Royal Indian Marine Survey Ship *Investigator*," by Dr. A. Alcock, F.R.S., illustrated; The Progressive Science Series:—"Vivisection," by Stephen Paget, and "Heredity," by Prof. J. Arthur Thomson, illustrated; "The Soil," by A. D. Hall; "Elements of Political Economy," by Dr. James Bonar; "Botany," by William Cross; "Introduction to Philosophy," by Dr. S. Rappoport; "Introduction to the Study of Animal Life," by Prof. W. B. Bottomley; "Plant Life," by Prof. W. B. Bottomley; "Telegraphs and Telephones," by Sir W. H. Preece, K.C.B., F.R.S.; "The Calculus for Artisans," by Prof. O. Henrici, F.R.S.; "Algebra," Part ii., by E. M. Langley and S. R. N. Bradly; "Geometry, an Elementary Treatise on Euclid and Geometrical Drawing," by S. O. Andrew; "The Book of Sir Marco Polo, the Venetian, concerning the Kingdoms and the Marvels of the East," translated and edited by the late Colonel Sir Henry Yule, K.C.S.I., revised throughout in the light of recent discoveries by Henri Cordier, with a Memoir of Henry Yule; "Animism: a Treatise on the Natural History of Religion, based on the Gifford Lectures delivered in Aberdeen in 1889-90 and 1890-91," by Prof. Edward Burnett Tylor, F.R.S., illustrated.

Messrs. T. Nelson and Sons will publish:—"In Flora's Realm: a Story of Flowers, Fruit and Leaves," by E. Step, illustrated.

Messrs. George Newnes, Ltd., announce:—"Gardens, Old and New," vol. ii., illustrated; "The Twentieth Century Citizen's Atlas," by J. G. Bartholomew; "A Book of Birds and Beasts," by Gambier Bolton, the famous photographer of wild animals, illustrated; Library of Useful Stories:—"The Story of Alchemy, or the Beginning of Chemistry," by M. M. Pattison Muir.

The Oxford University Press announces:—"A Text-Book on the Theory and Practice of Histology," by Gustav Mann; Schimper's "Geography of Plants," English edition, by Profs. Percy Groom and W. R. Fisher, illustrated; Goebel's "Organography of Plants," authorised English edition, by Prof. I. Bayley Balfour, F.R.S., part ii.

Messrs. C. Arthur Pearson, Ltd., call attention to:—"The Eldorado of the Ancients: Travels in Central Africa," by Dr. Carl Peters, illustrated; "Among Swamps and Giants in Equatorial Africa," by Major H. H. Austin, illustrated.

Messrs. G. P. Putnam's Sons announce:—"Spiritism or Telepathy, Results of Psychical Research," by Minot J. Savage; "Field Book of American Wild Flowers, with a short Description of their Character and Habits, a concise Definition of their Colours, and References to the Insects which Assist in their Fertilisation," by F. Schuyler Mathews, illustrated; "The Romance of the Colorado River: a Complete Account of the first Discovery and of the Explorations from 1540 to the Present Time, with Particular Reference to the two Voyages of Powell through the Line of the Great Canyons," by Frederick S. Dellenbaugh, illustrated; "The Home Life of the Wild Birds," by Francis H. Herrick, illustrated.

Mr. Grant Richards announces:—"Scientific Phrenology: a Practical Handbook," by Bernard Hollander, illustrated.

Among Messrs. F. E. Robinson and Co.'s announcements we observe:—"The Zoological Gardens of Europe, their History and chief Features," by C. V. A. Peel, illustrated.

Messrs. Smith, Elder and Co. will issue:—"The Lighthouse Work of Sir James Timmins Chance," by J. F. Chance, with two portraits.

Messrs. Swan Sonnenschein and Co., Ltd., announce:—"Aristotle's Psychology: a Treatise on the Principles of Life (*De anima* and *Parva Naturalia*)," translated and edited by Prof. William Hammond; "A History of Contemporary Philosophy," by Prof. Max Heinze, translated by Prof. William Hammond; "The Mind of Man: a Text-book of Psychology," by Gustav Spiller; "The Basis of Morality," by Arthur Schopenhauer, translated by Arthur Brodrick Bullock; "Contemporary Psychology," by Prof. Guido Villa, translated from the Italian by Harold Manacorda; "The Student's Text-book of Zoology," by Adam Sedgwick, F.R.S., vol. ii., illustrated; "Avenues to Health," by Eustace H. Miles; "British Moths," by Alfred H. Bastin, illustrated; "Specimens of Bushman Folklore," by Dr. W. H. J. Bleek and Miss L. C. Lloyd; "West African Folk Tales: as taken from the Mouths of the Temne Tribesmen," illustrated; "Fatigue," by Dr. Mosso, translated by W. B. Drummond; "Elementary Geometry: being a new Treatment of the Subject-Matter of Euclid (Books I. to IV.), specially Adapted for Use in Schools," by J. Elliott; and new editions of "Harlyn Bay and the Discoveries of its Prehistoric Remains," by the Rev. R. Ashington Bullen, illustrated; "School Hygiene: the Laws of Health in Relation to School Life," by Drs. Arthur Newsholme and Walter C. C. Pakes, illustrated; "Practical Pocket-book of Photography," by Dr. E. Vogel, translated and edited by E. C. Conrad, illustrated; "The Dynamo: How Made and How Used," by S. R. Bottone; "The Home Doctor," by Dr. F. R. Walters, illustrated; "Crustaceans and Spiders," by F. A. A. Skuse.

Mr. Fisher Unwin promises:—"Sand-Buried Ruins of Khotan," by M. Aurel Stein, illustrated; "Motor Cars and the Application of Mechanical Power to Road Vehicles," by Rhys Jenkins, illustrated.

Messrs. F. Warne and Co. announce:—"Rand Gold Mining," by John Stuart, illustrated; "The Little Folks' Picture Natural History: First Glimpses of the Animal World," by Edward Step.

Messrs. Whittaker and Co.'s announcements are:—"Experiments with Vacuum Tubes," by Sir David Salomons; "Hints to Automobilists," translated from the French of Baudry de Saunier by C. V. Biggs; "Practical Chemistry on the Heuristic Method," by Dr. W. C. Harris; "Elementary Practical Optics," by T. H. Blakesley; "Electric Traction," by J. H. Rider; "Electrical Engineers' Pocket-book," by Kenelm Edgcumbe; "Electric Lighting and Power Distribution," by W. Perren Maycock, vol. ii.; "Mechanical Refrigeration," by H. Williams; "Telephone Lines and Methods of constructing Them," by W. C. Owen; "Friction and its Reduction by Means of Oils, Bearings and Lubrication," by G. U. Wheeler.

THE BRITISH ASSOCIATION AT BELFAST.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY A. C. HADDON, M.A., SC D., F.R.S., M R.I.A., PRESIDENT OF THE SECTION.

So much has been written of late on totemism that I feel some diffidence in burdening still further the literature of the subject. But I may plead a slight claim on your attention, as I happen to be an unworthy member of the Crocodile kin of the Western tribe of Torres Straits, and I have been recognised as such in another island than the one where I changed names with Maino, the chief of Tutu, and thereby became a member of his kin.

I do not intend to discuss the many theories about totemism, as this would occupy too much time; nor can I profess to be able to throw much light upon the problems connected with it; but I chiefly desire to place before you the main issues in as clear a manner as may be, and I venture to offer for your consideration one way in and some ways out of totemism.

A few years ago M. Marillier wrote ("Rev. de l'Hist. des Religions," xxxvi. 1897, pp. 368, 369), that "totemism is one of the rare forms of culture: it is incapable of evolution and transformation, and is intelligible only in its relations with certain types of social organisation. When these disappear it also disappears. Totemism in its complete development is antagonistic alike to transformation or progress." In due course I shall describe how one people at least is emerging from totemism. At the outset I wish it to be distinctly understood that I do not regard this as the only way out; doubtless there have been several transformations, but a record of what appears to be taking place appeals more to most students than a guess as to what may have happened.

What is most needed at the present time is fresh investigation in the field. Those who are familiar with the literature of the subject are only too well aware of the imperfection of the available records. There are several reasons which account for this. Some of the customs and beliefs associated with totemism have a sacred significance, and the average savage is too reverent to speak lightly of what touches him so deeply. Natives cannot explain their mysteries any more than the adherents of more civilised religions can fully explain theirs. Further, they particularly dislike the unsympathetic attitude of most inquirers, and nothing shuts up a native more effectually than the fear of ridicule.

Language is another difficulty. Even supposing the white man has acquired the language, the vocabulary of the native is not sufficiently full or precise to explain those distinctions which appeal to us, but which are immaterial to him.

Granting the willingness of the native to communicate his ideas, and that the hindrance of language has been overcome, there remains the difficulty of the native understanding what it is the white man wishes to learn. If there is a practically insuperable difficulty in the investigator putting himself into the mental attitude of the savage, there is also the reciprocal source of error.

> "Oh, East is East, and West is West,
> And never the twain shall meet."

If Kipling is right for the civilised Oriental, how about those of lower stages of culture and more primitive modes of thought?

We must not overlook the fact that the majority of white men who mix with primitive folk are either untrained observers or their training is such that it renders them yet more unsympathetic—one might say antagonistic—to the native point of view. The ignorance and prejudice of the white man are great hindrances to the understanding of native thought.

When students at home sift, tabulate and compare the available records they get a wider view of the problems concerned than the investigator in the field is apt to attain. Generalisations and suggestions crystallise out which may or may not be true, but which require further evidence to test them. So the student asks for fresh observations and sends the investigator back to his field.

The term "totemic" has been used to cover so many customs and beliefs that it is necessary to define the connotation which is here employed.

It appears from Major J. W. Powell's recent account of totemism (*Man*, 1902, No. 75) that the Algonkin use of the term "totem" is so wide as to include the representation of the animal that is honoured (but he does not state that the animal itself is called a totem), the clay with which the person was painted, the name of the clan,[1] and that of the gens,[2] the tribal name, the names of shamanistic societies, the new name assumed at puberty, as well as the name of the object from which the individual named. He distinctly states, "We use the term 'totemism' to signify the system and doctrine of naming." I must confess to feeling a little bewildered by this terminology, and I venture to think it will not prove of much service in advancing our knowledge. It looks as if there had been some misunderstanding, or that the Algonkins employed the word "totem" to cover several different ideas because they had not definite terms with which to express them. Major Powell's definitions practically exclude those cults which are practised in various parts of the world, and which by the common consent of other writers are described as totemic.

Prof. E. B. Tylor has given (*Man*, 1902, No. 1; *cf. Journ.* Anthrop. Inst., xxviii. 1898. p. 138) the following clear exposition of his interpretation of the American evidence: "It is a pity that the word 'totem' came over to Europe from the Ojibwas through an English interpreter who was so ignorant as to confuse it with the Indian hunter's patron genius, his *manitu*, or 'medicine.' The one is no more like the other than a coat of arms is like a saint's picture. Those who knew the Algonkin tribes better made it clear that totems were the animal signs, or, as it were, crests, distinguishing exogamous clans; that is, clans bound to marry out of, not into, their own clan. But the original sin of the mistake of Long the interpreter has held on ever since, bringing the intelligible institution of the totem clan into such confusion that it has become possible to write about 'sex totems' and 'individual totems,' each of which terms is a self-contradiction. . . . Totems are the signs of intermarrying clans."

A reviewer in "L'Année Sociologique," ii. 1899, says (p. 202): "One must avoid giving to a genus the name of a species. It will be said these are merely verbal quibbles; but does not the progress of a science consist in the improvement of its nomenclature and in the classification of its concepts?"

Totemism, as Dr. Frazer and as I understand it, in its fully developed condition implies the division of a people into several totem kins (or, as they are usually termed, totem clans), each of which has one, or sometimes more than one, totem. The totem is usually a species of animal, sometimes a species of plant, occasionally a natural object or phenomenon, very rarely a manufactured object. Totemism also involves the rule of exogamy, forbidding marriage within the kin, and necessitating intermarriage between the kins. It is essentially connected with the matriarchal stage of culture (mother-right), though it passes over into the patriarchal stage (father-right). The totems are regarded as kinsfolk and protectors or benefactors of the kinsmen, who respect them and abstain from killing and eating them. There is thus a recognition of mutual rights and obligations between the members of the kin and their totem. The totem is the crest, or symbol of the kin.

Sometimes all the kins are classified into two or more groups; for example, in Mabuiag, in Torres Straits, there is a dual grouping of the kins, the totems of which are respectively land and water animals; and in speaking of the latter group my informant volunteered the remark, "They all belong to the water; they are all friends." On the mainland of New Guinea also I found that one group of the totems "stop ashore," while the other "stop in water." When no member of a group of kins in a community can marry another member of that same

[1] A group that reckons descent only through the mother.
[2] A group that reckons descent only through the father.

group, that group is termed a phratry. An Australian tribe is generally divided into two exogamous phratries.

North America is the home of the term "totem," and though typical totemism does occur there, it is often modified by other customs. In Australia we find true totemism rampant, and it occurs in Africa, where also it is subject to much modification. Quite recently the Rev. J. Roscoe has published an important paper (*Journ.* Anthrop. Inst., xxxii. 1902, p. 25) on the Baganda, in which he describes a perfectly typical case of totemism. Among the Baganda there are a number of kins each of which has a totem, *muziro.* The kin, *kika*, is called after its totem; no member of a kin may kill or eat his totem, though one of another kin may do so with impunity. No one mentions his totem. Old people affirm their fathers found some things injurious to them either as food or to their personal safety, and made their children promise not to kill or eat that particular thing. No man may marry into his mother's kin, because all the members of it are looked upon as sisters of his mother; nor may he marry into his father's kin except in the case of two very large kins. In Uganda, royalty follows the totem of the mother, whilst the common people follow the paternal totem. Each kin has its own special part of the country where the dead are always buried. For sympathy or assistance the member of a kin always turns to his particular kin. From what Mr. Roscoe says about the married women of the Green Locust kin, it is evident that the magical aspect of totemism is present as it is in Australia and Torres Straits. The Baganda are thus a true totemic people who are in an interesting transitional condition between matriarchy and patriarchy. Totemic practices also occur in various parts of Asia.

To put the matter briefly, totemism consists of the following five elements:—

(1) Social organisation with totem kinsmen and totem symbols.

(2) Reciprocal responsibilities between the kin and the totem.

(3) Magical increase[1] or repression of the totem by the kinsmen.

(4) Social duties of the kinsmen.

(5) Myths of explanation.

Totemism is only one of several animal cults, and it is now necessary to consider certain cults that have been termed totemic before I proceed with the main object of this Address.

Manitu (*Guardian Spirit*).

Very widely spread in North America was the belief in guardian spirits which appeared to young men in visions after prayer and fasting. It then became the duty of the youth to seek until he should find the animal he had seen in his trance; when found he must slay and preserve some part of it. In cases when the vision had been of no concrete form, a symbol was taken to represent it: this memento was ever after to be the sign of his vision, the most sacred thing he could ever possess, for by it his natural powers were so to be reinforced as to give him success as a hunter, victory as a warrior, and even power to see into the future.

The guardian spirit was obtained in various ways by different American tribes, but the dream apparition was the most widely spread. Dr. Frazer ("Totemism," 1887, pp. 2, 53) calls it "individual totem"; Miss Fletcher speaks of the object dreamed of (the *wahube* of the Omaha) as the "personal totem" or simply as the "totem"; it is termed by the Algonkin *manitu*, by the Huron *okki*, by the Salish Indians *sulia*, and *nagual* in Mexico. Perhaps it would be best to adopt either *wahube* or *manitu* to express the guardian spirit.

Miss Alice C. Fletcher finds that among the Omaha ("The Import of the Totem," Amer. Assoc. Adv. Sci., Detroit Meeting, August, 1897) those who have received similar visions, that is, those who have the same *wahube*, formed brotherhoods which gradually developed a classified membership with initiatory rites and other rituals. These religious societies acquired great power; still later, according to this observer, an artificial social structure, the "gens," was organised on the lines of the earlier religious societies. Each "gens" had its particular name, which referred directly or symbolically to its totem, and its members practised exogamy and traced their descent only through the father. "As totems could be obtained in but one way—through the rite of vision—the totem of a 'gens' must have come into existence in that manner, and must have represented the manifestation of an ancestor's vision, that of a man whose ability and opportunity served to make him the founder of a family." Mr. C. Hill-Tout (*Trans.* Roy. Soc. Canada, 2nd ser., vii., sect. 2, 1901, p. 6), in discussing the origin of the totemism of the aborigines of British Columbia, states: "There is little room for doubt that our clan totems are a development of the personal or individual totem or tutelar spirit, as this is in turn a development of an earlier fetishism."

Dr. F. Boas points out ("Report U.S. Nat. Mus.," 1895 (1897), pp. 322, 323, 334) that the tribes of the northern portion of the North Pacific group of peoples, such as the Tlingit, Haida and Tsimshian, have a maternal organisation with animal totems; the clans bear the names of their respective totems and are exogamous. The central tribes, particularly the Kwakiutl, show a peculiar transitional stage. The southern tribes have a purely paternal organisation, and their groups are simple village communities which are often exogamic.

Dr. Boas distinctly asserts (*l.c.*, p. 323) that "the natives do not consider themselves descendants of the totems; all endeavours to obtain information regarding the supposed origin of the relation between man and animal invariably led to the telling of a myth in which it is stated how a certain ancestor of the clan in question obtained his totem. . . . It is evident that legends of this character correspond almost exactly to the tales of the acquisition of manitows among the eastern Indians, and they are evidence that the totem of this group of tribes is in the main the hereditary manitow of a family.[1] This analogy becomes still clearer when we consider that each man among these tribes acquires a guardian spirit, but that he can acquire only such as belong to his clan. Thus a person may have the general crest of his clan, and besides use as his personal crest such guardian spirits as he has acquired. This accounts partly for the great multiplicity of combinations of crests on the carvings of these people."

Throughout a considerable portion of North America there appears to be a mixture of variously developed cults of the totem and of the *manitu.* It is not perhaps possible at present to dogmatise as to the relative chronology of these two cults. Personally I am in favour of the superior antiquity of the totem cult, as the conception of an individual spirit-helper appears to me to be of a higher grade than the ideas generally expressed by purely totemic peoples, or what may be gathered by implication from a study of their ceremonies.

The social organisation appears to be very weak in some Californian tribes; our knowledge of the Seri in this respect is very meagre, but Dr. Dixon definitely denies (*Bull.* Amer. Mus. Nat. Hist., xvii., pt. 2, 1902, p. 35) the existence of totemic grouping among the Maidu.

Accepting then for the present the priority of the totem cult, we find a substratum of totemism underlying many of the social organisations in North America. Religious societies are a noticeable feature of the social life of North-west America; those societies have the guardian spirit (*manitu*) as their central idea, but it appears as if the organisation is rooted in a clan (matriarchal totemic kin) system which has been smothered and virtually destroyed by the parasitic growth. The problems to be solved in North-west America are very complicated, and we must await with patience further researches. It is perfectly evident from the researches of Boas, Nelson, Hill-Tout and others that comparatively recent great changes have taken place. Dr. Boas indeed states that "the present system of tribes and clans (of the Kwakiutl) is of recent growth and has undergone considerable changes" (*l.c.*, p. 333). An interesting illustration of this is found in the alteration in the organisation of the (Kwakiutl) tribe during the season of the winter ceremonial. "During this period the place of the clans is taken by a number of societies, namely, the groups of all those individuals upon whom the same or almost the same power or secret has been bestowed by one of the spirits" (*l.c.*, p. 418). The characteristic North

[1] The first intimation of this aspect of totemism is entirely due to the researches of Messrs Spencer and Gillen ("The Native Tribes of Central Australia," 1899). Dr. J. G. Frazer, appreciating the value of these observations, extended the conception to totemism generally, *Journ.* Anthrop. Inst., xxviii. 1899, p. 285, read December 14, 1898; the *Fortnightly Review*, April, 1899, pp. 664, 665; *cf.* also "Israel and Totemism," by S. A. Cook, *Jewish Quart. Review*, April, 1902, pp. 25, 26 of reprint.

[1] But Mr. E. S. Hartland points out ("Folk-lore," xi 1900, p. 61) that we have clear evidence from the legends of the descent at all events of some of the clans from non-human ancestors; and Mr. Hill-Tout says: "Among the Salish tribes it is uniformly believed that in the early days, before the time of the tribal heroes or great transformers, the beings who then inhabited the world partook of the character of both men and animals, assuming the form of either apparently at will."

American idea of the acquisition of the *manitu* was evidently also fundamental among the Kwakiutl, as all their tales refer to it and the whole winter ceremonial is based on it.

I agree in the main with Mr. Hartland ("Folk-lore," xi. p. 68) in thinking that, "whether or no totemism was anciently a part of the tribal organisation, the *manitu* conception is of modern date. It is part of the individualism which is tending, not among these tribes only, to obscure the older communistic traditions."

Nyarong.

Allied to the *manitu* of North America is the *nyarong*, or spirit-helper, of the Iban (Sea Dayaks) of Sarawak. The Iban believe that the spirit of some ancestor or dead relative may come to them in a dream, and this *nyarong* becomes the special protector of the individual. An Iban youth will often retire to some lonely spot or mountain-top and live for days on a very restricted diet in his anxiety to obtain a vision. This custom is called *mampok*. On the following day the dreamer searches for the outward and visible form of the *nyarong*, which may be anything from a curious natural object to some one animal. In such cases the *nyarong* hardly differs from a fetish. In other cases, as the man is unable to distinguish the particular animal which he believes to be animated by his *nyarong*, he extends his regard and gratitude to the whole species. In some instances all the members of a man's family and all his immediate descendants, and if he be a chief all the members of the community over which he rules, may came to share the benefits conferred by the *nyarong* and pay respect to the species of animal in one individual of which it is supposed to reside. "In such cases," Drs. Hose and McDougall remark (*Journ.* Anthrop. Inst., xxxi. 1901, p. 210), "the species approaches very closely the clan totem in some of its varieties." Here we have a parallel to the North American custom, but the later stages are not carried as far.

Personally I concur in the opinion expressed by Drs. Hose and McDougall that there is no proof that the peculiar regard paid in Sarawak to animals, the sacrifice of animals to gods or spirits, the ceremonial use of the blood of these sacrificed animals are survivals of a fully developed system of totem worship now fallen into decay. It is very significant that the magical and social aspects of totemism are entirely lacking.

Those who have read Miss Alice Fletcher's sympathetic account of "The Import of the Totem" (Amer. Assoc. Adv. Sci., Section Anthropology, Detroit Meeting, August, 1897) can scarcely fail to recognise that the moral support due to a belief in the guidance and protection of a *wahube* ("personal totem") is of great importance to the individual, and would nerve him in difficulty and danger, and thus proving a very present help in time of need it would surely justify its existence in a most practical manner and consequently be of real utility in the struggle for existence—a struggle which in man has a psychical as well as a material aspect.

The advantages of totemism are many, but most of them are social and benefit the special groups or the community at large. The hold that the *manitu* has on the individual consists in its personal relation; the man feels that he himself is helped, and I suspect this is the main reason why it supplants totemism. I believe Mr. Lang some years ago suggested the term *manituism* for this cult. If this name be not accepted I venture to propose the revival of the word "daimon" (δαίμων) to include the *manitu*, *nyarong* and similar spirit-helpers, and "daimonism" as the name of the cult.

Theriomorphic Ancestor Worship.

Dr. Frazer calls attention (*Man*, 1901, No. 3) to a publication by Dr. G. McCall Theal ("Records of South-eastern Africa," vii. 1901) in which he describes the tribal veneration for certain animals, *siboko*. The Bantu believed that the spirits of the dead visited their friends and descendants in the form of animals. Each tribe regarded some particular animal as the one selected by the ghost of its kindred, and therefore looked upon it as sacred. Dr. Frazer says: "Thus the totemism of the Bantu tribes of South Africa resolves itself into a particular species of the worship of the dead; the totem animals are revered as incarnations of the souls of dead ancestors. This entirely agrees with the general theory of totemism suggested by the late S. G. A. Wilken and recently advocated by Prof. E. B. Tylor" (*Journ.* Anthrop. Inst., xxviii. p. 146). But is this totemism? The *siboko* are the residences of the ancestral spirits of the tribe, not of a clan; there is no mention of *siboko* exogamy. Is this anything more than theriomorphic ancestor worship? There can, however, be little doubt that true totemism did occur, and probably universally so, among the Bantu people; but some of the tribes appear to be in a transitional state, and others have doubtless passed beyond typical totemism. The decay of the Bantu totemism in South Africa appears to have been mainly due to a patriarchal organisation combined with a pastoral life.[1]

In describing Dr. Wilken's theory that the doctrine of the transmigration of souls affords the link which connects totemism with ancestor worship, Prof. Tylor concludes as follows: "By thus finding in the world-wide doctrine of soul-transference an actual cause producing the two collateral lines of man and beast which constitute the necessary framework of totemism, we seem to reach at least something analogous to its real cause." I have already expressed my belief that the animal cults of the Malay Archipelago, so far as they are known at present, cannot be logically described as totemism, and the majority of the peoples of this area have so long passed out of savagery that we are hardly likely to find here an unequivocal clue to the actual origin of totemism.

The reverence paid to particular animals or plants by certain groups of people in Fiji may, as Mr. Lorimer Fison says, ("Ann. Rep. Brit. New Guinea," 1897-98, p. 136) "look like reminiscences" of totemism, but he has "no direct evidence." It surely belongs to the same category as the Samoan custom of which Dr. George Brown writes (*ibid.*, p. 137), "In Samoa every principal family had some animal which they did not eat, and I have always regarded this as meaning, not that they thought the animal divine, or an object of worship, but that it was the 'shrine' in which their ancestral god had dwelt, or which was associated with some fact in their past history which had led them to adopt it as their totem." An opinion which Prof. Tylor has independently expressed (*Journ.* Anthrop. Inst., xxviii. p. 142), but he naturally dissents from the incarnate god being termed a "totem."

I agree with Dr. Codrington ("The Melanesians," 1891, p. 32) in doubting whether the evidence warrants a belief in totemism as an existing institution in the Southern Solomon Islands. I suspect that totemism has been destroyed over a considerable portion of Melanesia by the growth of secret societies as well as by theriomorphic ancestor worship. Herr R. Parkinson (*Abh. Ber. k Zool. Anth. Eth. Mus. Dresden*, vii. 1899, Nr. 6), however, proves true totemism in the Northern Solomon Islands as the Rev. B. Danks had previously done (*Journ.* Anthrop. Inst., xviii. 1889, p. 281) for New Britain, Duke of York Island and New Ireland.

The more one looks into the evidence the more difficult is it to find cases of typical totemism; almost everywhere considerable modification has taken place, often so much so that the communities cannot logically be called totemistic. The magical increase of the totem by the clansmen does not appear to be common, but that may be due to its having been overlooked; on the other hand, magic may be performed against the totems to prevent them from injuring the crops, as in the case of the "Reptile people" of the Omaha (J. O. Dorsey, "Ann. Rep. Bureau Ethnol.," 1881-82 (1884), p. 248).

Animal Brethren.

Throughout South-eastern Australia and probably elsewhere in that continent, there is a peculiar association of a species of animal, unusually a bird, with each sex. To take two examples given by Mr. A. W. Howitt (*Journ.* Anthrop. Inst., xv. 1886, p. 416), "the bird totems of the Kurnai are the Emu, Wren and the Superb Warbler, which are respectively the 'man's brother' and 'woman's sister.' . . . When we turn to the Kulin, we find both the Kurnai totems in just the same position. In addition there are also a second male and female totem, namely, the Bat and the small Night Jar." Mr. Howitt is careful to point out, "They are not true totems in the sense that these represent subdivisions of the primary classes; yet they are true totems in so far that they are regarded as being the 'brothers' and 'sisters' of the human beings who bear their names." Mr. A. L. P. Cameron (*ibid.*, xiv. 1885, p. 350) also states that these are "something different from ordinary totems." Later Mr. Howitt (*ibid.*, xviii. 1888, pp. 57, 59) says: "Among the Wotjobaluk tribe which have a true totemic

[1] E. Durkheim, "L'Année Sociologique," v. 1902, p. 330; *cf.* also F. B. Jevons, "Introduction to the History of Religion," 1902, pp. 155, 158.

system these were real totems although of a peculiar kind. They were called *yaur*, or 'flesh,' or *ngirabŭl*, or *mir*, just as were the totems proper. The only difference was that the Bat was the brother of all the men, while any one totem was the brother only of the men who bore it as their totem. . . . It is evident that the institution of the 'man's brother' and the 'woman's sister' as totems is very widespread throughout Australia. I have traced it over an extent of about a thousand miles and in tribes having marked differences in language and in social organisation. It seems to be very persistent and enduring, for it remained among the Kurnai in full force after the ordinary social organisation in class divisions and totems had become extinct." Mr. Howitt speaks of these as "abnormal totems," and Dr. Frazer ("Totemism," p. 51; "The Golden Bough," iii. p. 416) calls them "sex totems." As it appears most desirable to distinguish between this cult, which is confined to Australia, and true totemism, I propose, in default of a distinctive native term, to call these reverenced animals "animal brethren." Although the natives do not appear to distinguish nominally between these animal brethren and ordinary totems, it does not follow they are to be considered as the same. I am calling attention to an analogous confusion of terms in the totemism of Torres Straits.

I must now pass on to a further consideration of true totemism as understood by Tylor, Frazer, Lang, Hartland, Jevons, Durkheim and others, as it is impossible within the limits of an Address to give an account of all the varieties of pseudo-totemism.

A Suggestion concerning the Origin of Totemism.

I take this opportunity to hazard a suggestion for a possible origin of one aspect of totemism. Primitive human groups, judging from analogy, could never have been large, and the individuals comprising each group must have been closely related. In favourable areas each group would have a tendency to occupy a restricted range owing to the disagreeable results which arose from encroaching on the territory over which another group wandered. Thus it would inevitably come about that a certain animal or plant, or group of animals or plants, would be more abundant in the territory of one group than in that of another. To take a clear example, the shore-folk and the river-folk would live mainly on different food from each other and both would have other specialities than fell to the lot of the jungle-folk. The groups that lived on the seashore would doubtless have some natural vegetable products to supplement their animal diet, but the supply would probably be limited alike in quantity and variety. Even they would scarcely have unlimited range of a shore line, and there would be one group of shore-folk that had a speciality in crabs, another would have shell-beds, while a third would own sandy shores which were frequented by turtle. A similar natural grouping would occur among the jungle-folk; sago flourishes in swampy land, certain animals frequent grassy plains, others inhabit the dense scrub, bamboos grow in one locality, various kinds of fruit trees thrive best in different soils; the coastal plains, the foot hills, the mountains, each has its characteristic flora and fauna. There is thus no difficulty in accounting for numerous small human groups each of which would be largely dependent upon a distinctive food supply the superfluity of which could be bartered [1] for the superfluities of other groups. These specialities were not confined to food alone; for example, the shore-folk would exchange the shells they collected for the feathers obtained from the jungle-folk.

It may be objected that in the great prairies and steppes of America, Eurasia and Australia the natural products are very uniform; but these areas are not thickly populated, and in most cases they probably were only inhabited when the pressure of population in the localities with more varied features forced migration into the open. Certainly these were never the primitive homes of man.

In a recent paper read before the Folklore Society, Mr. Andrew Lang put forward the hypothesis that while each primitive human group called itself "the men," they named the surrounding groups from the names of animals or plants, and hence arose totemism. The idea that there was an intimate connection between the group and the object from which they were nicknamed would soon be developed, and myths of origin would spring up to account for the name. Mr. Lang's theory, still unpublished, regards totem names as given from without for a variety of reasons, amongst which, I understand, he includes my own suggestion. His conjecture is based on the similar names, or sobriquets, of villages in the folklore, or *blason populaire*, of France and England, which, again, is almost identical with the extant names of Red Indian totem kindred now counting descent in the male line. Similar phenomena occur in Melanesia with female kin. Mr. Lang is rather indifferent to the causes of the name-giving so long as the name-giving comes from without and applies to groups, not to individuals.

To return to my suggestion. Among the shore-folk the group that lived mainly on crabs and occasionally traded in crabs might well be spoken of as the "crab-men" by all the groups with whom they came in direct or indirect contact. The same would hold good for the group that dealt in clams or in turtle, and reciprocally there might be sago-men, bamboo-men, and so forth. It is obvious that men who persistently collected or hunted a particular group of animals would understand the habits of those animals better than other people, and a personal regard for these animals would naturally arise. Thus from the very beginning there would be a distinct relationship between a group of individuals and a group of animals or plants, a relationship that primitively was based, not on even the most elementary of psychic concepts, but on the most deeply seated and urgent of human claims, hunger.

There is scarcely any need to point out that the association of human groups with fearsome animals would arise by analogy very early. Hence tiger-men and crocodile-men would restrain the ravages of those beasts (Dr. Frazer, *Fortnightly Review*, 1899, p. 835, describes this as the negative or remedial side of totemic magic); but I take it this was not as primitive as the nutritive alliances. The relation between groups of men and the elements has a purely economic basis; for example, rain is rarely required for itself, but as a means for the increase of vegetable food; similarly the fisherman wants a wind to enable him to get to and from his fishing grounds.

The next phase is reached when man arrived at elementary metaphysical conceptions and endeavoured by sympathetic or symbolic magic to increase his food supply. Naturally the food or product that each group would endeavour to multiply would be the speciality or specialities of that group, and for this practice we now have demonstrative evidence. Though this may be an early phase of totemism, I do not consider it the earliest; it can scarcely be the origin of totemism, but it doubtless helped to establish and organise the system.

The essential difference between the view advocated by Dr. Frazer (*loc. cit.*, 1899, p. 835) and that here suggested is that according to him totemism "is primarily an organised and cooperative system of magic designed to secure for the members of the community, on the one hand, a plentiful supply of all the commodities of which they stand in need, and, on the other hand, immunity from all the perils and dangers to which man is exposed in his struggle with nature. Each totem group, on this theory, was charged with the superintendence and control of some department of nature from which it took its name, and with which it sought, as far as possible, to identify itself." Whereas I suggest that the association between a group of men and a species of animals or plants was the natural result of local causes, and that departments of nature were not "assigned to a particular group" of men. I think it is scarcely probable "that in very ancient times communities of men should have organised themselves more or less deliberately for the purpose of attaining objects so natural by means that seemed to them so simple and easy." I suspect that if there was any deliberate organisation it was in order to regulate already existing practices.

To us it might appear that these magical practices could be undertaken by anyone, but this does not seem to have been an early conception. As far as we can penetrate the mind of existing backward man, there is a definite acknowledgment of the limit of his own powers. The members of one group can perform a certain number of actions; there are others that they cannot undertake. One group of men, for example, may ensure the abundance of a certain kind of animal, but another will have power over the rain. An interesting example of this limitation is afforded at Port Moresby, in British New Guinea, where the Motu immigrants have to buy fine weather for their trading voyages from the sorcerers of the indigenous agricultural Koitapu (J. Chalmers, "Pioneering in New Guinea," 1887, p. 14).

[1] It may be objected that the idea of barter is by no means primitive; but as I believe that sociability was a fundamental characteristic of primitive man I can see no reason why it should not have occurred quite early in a rudimentary sort of way.

The remarkable researches of Messrs. Spencer and Gillen in Central Australia prove that it is the function of the kinsmen of a particular totem to perform what are known as *intichiuma* ceremonies, the object of which is to cause the abundance of the species of animal or plant which is the totem of that kin. The descriptions of these ceremonies are well known to students.[1] I have adduced further evidence of a like nature,[2] and from what Mr. Roscoe has found in Uganda we may expect other examples from Africa.

It may be that in some, possibly in all, of the instances of sympathetic and symbolic magic there is a belief that wind or sun, animal or plant, or whatever the objects may be, are animated by spirits akin to those of humankind; but even so, as Dr. Frazer[3] points out, the action of the magician is a direct one; it does not imply the assistance of other powers who can control the body or spirit of those objects. The data from Australia and Torres Straits point to the conclusion that there is a magical aspect of totemism, which is of great economic importance, and there is no evidence that the officiators at these ceremonies acknowledge the assistance of spiritual powers resident either within the objects themselves or in the form of independent, more or less supreme beings. The existing data do not deny their existence, they simply ignore them in the ceremonies, and so far they are practically non-existent.

According to the suggestion I have ventured to make, the primitive totemic groups ate their associated animals or plants; indeed, these were their chief articles of diet. Messrs. Spencer and Gillen point out[4] that while amongst most Australian tribes a man may not eat his totem, amongst the Arunta and other tribes in the centre of the continent there is no restriction according to which a man is altogether forbidden to eat his totem. On the other hand, though he may, only under ordinary circumstances, eat very sparingly of it, there are certain special occasions on which he is obliged by custom to eat a small portion of it, or otherwise the supply would fail. The Arunta are a peculiar people, while they may be primitive in some respects; in others they are not so, as also has been pointed out by Durkheim ("L'Année Sociologique," v. 1902). According to the strict definition of the term, they are not even a totemic people. Judging from the evidence of the legends of the Alcheringa time and the traces of group marriage and mother right, Mr. Hartland ("Folk-lore," xi. 1900, pp. 73–75) is of opinion that the present disregard by the Arunta of the totem in marriage is a stage in the sloughing of totemism altogether, whereas the *engwura*, or final initiation ceremonies, indicate that "the organisation is undergoing a slow transformation into something more like the so-called secret societies of the British Columbian tribes."

The eating of what are evidently the totem animals by the Arunta may possibly be a persistence from an earlier phase, but, without doubt, the totem taboo is characteristic of totemism in full sway.[5] We have evidence to show that under certain conditions the totem taboo may break down, but this is a later transformation, and indicates a breaking up of the rigid observance of totemism.

Mr. Lang ("Magic and Religion," 1901, pp. 264, 265) has made a simple suggestion to account for the origin of the totem taboo. He says: "These men therefore would work the magic for propagating their kindred in the animal and vegetable world. But the existence of this connection would also suggest that, in common decency, a man should not kill and eat his animal or vegetable relations. In most parts of the world he abstains from this uncousinly behaviour; among the Arunta he may eat sparingly of his totem, and must do so at the end of the close-time or beginning of the season. He thus, as a near relation of the actual kangaroo or grubs, declares the season is open, now his neighbours may begin to eat grubs or kangaroos; the taboo is off." Dr. Frazer puts forth two suggestions (*Fortnightly Review*, 1899, pp. 838–40): the one is that as animals do not eat their own kind, so man thought it inconsistent to eat his totem kin; the other is a hypothetical idea of conciliation.

1 Baldwin Spencer and F. J. Gillen, "The Native Tribes of Central Australia," 1899; *cf.* also J. G. Frazer, *Fortnightly Review*, 1899, pp. 648, 835.

2 "Folk-lore," xii. 1901, p. 230, and "Report Camb. Anthrop. Expedition to Torres Straits," vol. v. (in the press).

3 *Loc. cit.*, 1899, p. 657.

4 *Loc. cit.*, pp. 73, 167

5 I am fully aware that this appears to cut the ground from under my suggestion; but the latter deals with incipient totemism, and I do not see why the totem taboo should not have arisen from several causes.

I have barely touched upon the relation of social organisation, with its marriage taboo, to totemism. It is by no means certain that the social regulations and customs, which are so much in evidence in a fully developed totemic society, were primitively connected with totemism. So far as the Arunta are concerned, Messrs. Spencer and Gillen believe (*Journ.* Anthrop. Inst., xxviii. 1899, pp. 277, 278) the "totemism appears to be a primary, and exogamy a secondary, feature . . . and that exogamic groups were deliberately introduced so as to regulate marital relations." But is this primitive?

If one admits that mankind was originally distributed in small groups, which must have consisted of near kin, it does not seem difficult to imagine that marriage would more likely take place between members of contiguous groups rather than within the groups themselves. The attraction for novelty must always have operated, and in the struggle for existence there was always one advantage to be gained by alliances between neighbouring groups, not only from a commissariat point of view, but for offensive and defensive purposes. There is, of course, the converse of this, as wife-stealing would lead to feuds; perhaps daughter-abduction was more frequent, and this probably was not regarded as an offence so serious that a mild scrimmage would not set matters right. It would not take long for wont to crystallise into rigid custom, and custom is always supported by public opinion.

Social regulations must be later than social conditions, and I suspect that the privileges and taboos which run through the social aspect of totemism first arose when totemic groups were in process of aggregation into more complex communities, and afterwards gradually became fixed into a system.

Hero-cults.

The facts to which I have hitherto directed your attention fall well within the sphere of totemism, but I wish now to indicate two interesting departures from typical totemism, both of which occur among the Western tribe of Torres Straits.

I have alluded to the dual grouping of the totem kins at Mabuiag, and an analogous arrangement occurred in the other islands; I propose to speak of each group of kins as a phratry. Strictly speaking, a phratry is a group of exogamous kins within a community; that is, no member of a group of kins (or phratry) could marry another person belonging to the same phratry. The evidence that this is or was the case in the Western tribe of Torres Straits is strong, but it is not absolutely proven.

In Yam, as in the other islands, there is at least one *kwod*, or taboo ground, where sacred ceremonies were held. In the principal *kwod* in Yam there was formerly a low fence surrounding a space about thirty-five feet square in which were the shrines of the two great totems of the island. All that now remains is several heaps of great Fusus shells.

Two of the heaps are about twenty-five feet in length. Formerly at the southerly end of each long row of shells was a large turtle-shell (tortoise-shell) mask representing respectively a crocodile and a hammer-headed shark. These were decorated in various ways, and under each was a stone in which the life of the totem resided; stretching from the front end of each mask was a cord to which numerous human lower jaw-bones were fastened, and its other end was attached to a human skull, which rested on a stone. Beside the shrine of the hammer-headed shark was a small heap of shells which was the shrine of a sea-snake, which was supposed to have originated from the shark. These shrines were formerly covered over by long low huts, which like the fence were decorated with large Fusus shells.

Outside the fence were two heaps of shells which had a mystical connection with the shrine; they were called the "navels of the totems."

I have referred to the *intichiuma* ceremonies of the Arunta tribe of Central Australia as being magical rites undertaken by certain kinsmen for the multiplication of the totems. In some cases, apparently, the ceremonies may take place wherever the men happen to be camping; in other cases there are definite localities where they must be performed, as there are in these places certain stones, rocks or trees which are intimately connected with the magical rites. These spots may be spoken of as shrines. In the island of Mabuiag the magical ceremony for the alluring of the dugong was performed by the men of that kin in their own *kwod*, which was a fixed spot; and doubtless this was the case in the other islands of Torres Straits, for even

in the small islands there was a tendency to a territorial grouping of the kins. This localisation of a totem cult has proceeded one step further in Yam Island. Here we have a dual synthesis. The chief totem of each group of kins is practically alone recognised; in other words, the various lesser totems are being absorbed by two more important totems. Each totem has a distinct shrine, and the totem itself, instead of being a whole species, is visualised in the form of a representation of an individual animal, and this image was spoken of as the totem (*augud*). Indeed, the tendency to concretism had gone so far that the life of the *augud* was supposed to reside in the stone that lay beneath the image,[1] and certain heaps of shells were the navels of the totems, a further linkage of the totem to that spot of ground.

A suggestion as to the significance of this transformation is not lacking. There are various folk-tales concerning a family of brothers who wandered from west to east across Torres Straits. Some of them were, in a mysterious way, sharks as well as men. The two brothers who went to Yam were called Sigai and Maiau, and each became associated, in his animal form, with one of the two phratries. The shrines in the *kwod* were so sacred that no women might visit them, nor did the women know what the totems were like. They were aware of Sigai and Maiau, but they did not know that the former was the hammer-headed shark and the latter was the crocodile; this mystery was too sacred to be imparted to the uninitiated. When the totems were addressed it was always by their hero names, and not by their animal or totem names.

Malu, another of these brothers, introduced the cult that bears his name to the Murray Islanders, who form part of the Eastern tribe. He also was identified with a hammer-headed shark. Totemism, as such, had practically disappeared from Murray Island before the advent of the white man, and the great ceremonies at the initiation of the lads into the Malu fraternity were a main feature of the religion of these people.

In Yam totemism was merging into a hero cult; in Murray Island the transformation was accomplished; the one had replaced the other.

In Mabuiag, one of the Western Islands, there was a local hero named Kwoiam whose deeds are narrated in a prose epic. Kwoiam made two crescentic ornaments of turtle-shell, which blazed with light when he wore them at night-time, and which he nourished with the savour of cooked fish. These ornaments were called totems (*augud*)—presumably because the natives did not know by what other sacred name to call them—and they became the insignia of the two groups of kins of Mabuiag. The crescent which was worn above Kwoiam's mouth was regarded as the more important, and those kins which had land animals for their totems were called from it "the children of the great totem," but the water group was called "the children of the little totem." There is reason to believe that the dual grouping of the kins is ancient. The erecting Kwoiam's emblems as the head totems of the two groups of kins must be comparatively recent. Here, again, the primitive association of a group of men with a group of natural objects obtains in the small groups or totem-kins, but in the larger synthesis a manufactured object replaces a group of animals, and this object possesses definite magical powers. There were two navel-shrines connected with the cult of Kwoiam, which were constructed to show that the two *augud* were born there. When it was deemed necessary to fortify the *augud*—that is, the emblems—they were placed on their respective navel-shrines. Further, in Muralug and the adjacent islands Kwoiam himself was a totem (*augud*). Thus in the westernmost islands of the Western tribe the transition from totemism to hero-worship was in process of evolution till it was arrested by the coming of the white man.

To what was this transformation due? It is not very easy to answer this question. We have evidence that in comparatively recent times a change took place in the social organisation of the people, and that the former matriarchal conditions had been replaced by patriarchal. Although superficially the marriage system of the Western tribe appears to be regulated by totemism, Dr. Rivers has found[2] that it is really a relationship system, and that descent, rather than totemism, is the regulating factor. The Eastern tribe, as represented by the Murray Islanders, had progressed further along this road than had the Western tribe. Such a change as this could not fail to have a disturbing effect upon other old customs.

The folk-tales that I collected clearly indicate a migration of culture from New Guinea to the Western tribe, and from the Western tribe to the Eastern tribe. I believe I can demonstrate the migration from New Guinea of a somewhat broad-headed people that spread over the Western Islands but barely reached Murray Island. It is conceivable that the culture myths have reference to this migration, and that the gradual substitution of a hero cult for totemism may be part of the same movement; but, on the other hand, this social and religious change is most thorough in Murray Island, where, I imagine, the racial movement has been least felt. The isolation of Murray Island from outside disturbing factors is very complete, and, being but a small island, a change once started might take place both rapidly and effectively.

It is interesting to note that the totem heroes of the Western tribe were invoked when their votaries were preparing to go to war. I obtained the following prayer in Yam Island:—"O *Augud* Sigai and O *Augud* Maiau, both of you close the eyes of those men so that they cannot see us," which had for its intent the slaughtering of the enemy without their being able to make a defence. I was informed that when the Yam warriors were fighting they would also call on the name of Kwoiam, who belonged to another group of islands, and on Yadzebub, a local warrior. Yadzebub was always described as a "man," whereas Kwoiam and Sigai were relegated to a "long time" back. From the folk-tales it is evident that Sigai and Maiau are more mythical or mysterious than Kwoiam. We thus have an instructive series: Yadzebub, the local famous man; Kwoiam, the hero, who was also a totem to other people; and Sigai and Maiau, the local totem heroes whose cult was visualised in turtle-shell images, and the life of each of whom resided in a particular stone. Perhaps it would be more correct to speak of this as the grafting of a new cult on totemism rather than to describe it as an evolution of totemism. A transformation has certainly occurred, but it does not appear to me to be a gradual growth—a metamorphosis in the natural history sense of the term—so much as the pouring of new wine into old bottles.

I hope on another occasion to deal with the question of religious and secret societies, as the growth of these has invariably disintegrated whatever antecedent totemism there may have been.

It is highly probable that something like what was taking place in Torres Straits has occurred elsewhere, but I cannot now enter into a comparative study of the rise of hero cults.

Local or Village Exogamy.

I have more than once ("Folk-lore," xii. 1901, p. 233; "Head-hunters, Black, White, and Brown," 1901, p. 258) called attention to the fact that among some Papuans marriage restrictions are territorial and not totemic. Dr. Rivers (*Journ.* Anthrop. Inst., xxx. 1900, p. 78) has shown that in Murray Island, Eastern tribe of Torres Straits, marriages are regulated by the places to which natives belong. A man cannot marry a woman of his own village or of certain other villages. The totemic system which probably at one time existed in this island appears to have been replaced by what may be called a territorial system. A similar custom occurs in the Mekeo district of British New Guinea, and it is probably still more widely distributed.

I was informed by a member of the Yaraikanna tribe of Cape York, North Queensland, that children must take the "land" or "country" of their mother; all who belong to the same place are brothers and sisters, a wife must be taken from another "country" ("Brit. Assoc. Report," Dover, 1899, p. 585); thus it appears their marriage restrictions are territorial and not totemic. The same is found amongst the Kurnai and the Coast Murring tribe in New South Wales (Frazer, "Totemism," p. 90).

At Kiwai, in the delta of the Fly River, B.N.G., all the members of a totemic group live together in a long house which is confined to that group. I have also collected evidence which proves there was a territorial grouping of totemic clans among the Western tribe of Torres Straits ("Reports Camb. Anthrop. Expedition to Torres Straits," v. in the press).

Within a comparatively small area we have the following conditions:—

[1] For the keeping of a soul in an external receptacle, and for Dr. Frazer's views on its bearing on totemism, *cf. Fortnightly Review*, May, 1899, p. 844; "The Golden Bough," iii. 1900, pp. 418–422; and S. A. Cook, *Jewish Quart. Review*, 1902, p. 34 of reprint.

[2] "Reports Camb. Anthrop. Expedition to Torres Straits," v. "Kinship" (in the press).

(1) A typical totemic community with totem-kin houses (Kiwai).

(2) A typical totemic community with territorial grouping of the kins. Although there is totem exogamy, the marriage restrictions are regulated by relationship. The former mother-right has comparatively recently been replaced by father-right, but there are many survivals from matriarchy (Western tribe, Torres Straits).

(3) A community in which totemism has practically lapsed, with village exogamy and marriage restrictions regulated by relationship, patriarchy with survivals from matriarchy (Eastern tribe, Torres Straits).

(4) Total absence of totemism (?), village exogamy (Mekeo).

I do not assert this is a natural sequence, but it looks like one, and it appears to indicate another of the ways out of totemism. It is suggestive that this order also indicates the application of the several peoples to agriculture: the people of Kiwai are semi-nomadic, those of the Mekeo district are firmly attached to the land. This constraint of the soil must have operated in a similar manner elsewhere (*cf.* "L'Année Sociologique," v. 1902, pp. 330, 333). The territorial exogamy occasionally found in Australia cannot be explained as being due to agriculture; a rigid limitation of hunting grounds may here have had a similar effect.

In offering these remarks to-day I desire, above all, to impress on you the need there is for more work in the field. When one surveys the fairly extensive literature of totemism one is struck with the very general insufficiency of the evidence; as a matter of fact, full and precise information is lamentably lacking. The foundations upon which students at home have to build their superstructures of generalisation and theory are usually of too slight a character to support these erections with much chance of their permanence. There is only one remedy for this, and that is more extensive and more thorough field work. The problems connected with totemism bear upon many of the most important phases in the social and religious evolution of man, the solution of which can only be obtained within the space of a few years. The delay of each year in the investigation of primitive peoples means that so much less information is possible to be obtained. There is no exaggeration in this. Those who have a practical experience of backward man and who have travelled in out-of-the-way places can testify as to the surprising rapidity with which the old order changeth. In sober earnestness I appeal to all those who are interested in the history and character of man, whether they be theologians, historians, sociologists, psychologists or anthropologists, to face the plain fact that the only available data for the solution of many problems of the highest interest are daily slipping away beyond recovery.

SECTION I.

PHYSIOLOGY.

Opening Address by W. D. Halliburton, M.D., F.R.S., Professor of Physiology in King's College, London, President of the Section.

The Present Position of Chemical Physiology.

An engineer who desires to thoroughly understand how a machine works must necessarily know its construction. If the machine becomes erratic in its action, and he wishes to put it into proper working order, a preliminary acquaintance with its normal structure and function is an obvious necessity.

If we apply this to the more delicate machinery of the animal body, we at once see how a knowledge of function (physiology and pathology) is impossible without a preliminary acquaintance with structure or anatomy.

It is therefore not surprising, it is indeed in the nature of things, that physiology originated with the great anatomists of the past. It was not until Vesalius and Harvey by tedious dissections laid bare the broad facts of structure that any theorising concerning the uses of the constituent organs of the body had any firm foundation.

Important and essential as the knowledge is that can be revealed by the scalpel, the introduction and use of the microscope furnished physiologists with a still more valuable instrument. By it much that was before unseen came into view, and microscopic anatomy and physiology grew in stature and knowledge simultaneously.

The weapons in the armoury of the modern physiologist are multitudinous in number and complex in construction, and enable him in the experimental investigation of his subject to accurately measure and record the workings of the different parts of the machinery he has to study. But preeminent among these instruments stands the test-tube and the chemical operations typified by that simple piece of glass.

Herein one sees at once a striking distinction between the mechanism of a living animal and that of a machine like a steam engine or a watch. It is quite possible to be an excellent watchmaker or to drive a steam engine intelligently without any chemical knowledge of the various metals that enter into its composition. In order to set the mechanism right if it goes wrong, all the preliminary knowledge which is necessary is of an anatomical nature. The parts of which an engine is composed are stable; the oil that lubricates it and the fuel that feeds it never become integral parts of the machinery. But with the living engine all this is different. The parts of which it is made take up the nutriment or fuel and assimilate it, thus building up new living substance to replace that which is destroyed in the wear and tear associated with activity. This condition of unstable chemical equilibrium is usually designated metabolism, and metabolism is the great and essential attribute of a living as compared with a non-living thing.

It seems childish at the present day, and before such an audience as this, to point out how essential it is to know the chemical structure as well as the anatomical structure of the component parts of the body. But the early anatomists to whom I have alluded had no conception of the connection of the two sciences. Speaking of Vesalius, Sir Michael Foster says: "The great anatomist would no doubt have made use of his bitterest sarcasms had someone assured him that the fantastic school which was busy with occult secrets and had hopes of turning dross into gold would one day join hands in the investigation of the problems of life with the exact and clear anatomy so dear to him." Nor did Harvey, any more than Vesalius, pay heed to chemical learning. The scientific men of his time ignored and despised the beginning of that chemical knowledge which in later years was to become one of the foundations of physiology and the mainstay of the art of medicine.

The earliest to recognise this important connection was one whose name is usually associated more with charlatanry than with truth, namely, Paracelsus, and fifty years after the death of that remarkable and curious personality his doctrines were extended and developed by van Helmont. In spite, however, of van Helmont's remarkable insight into the processes of digestion and fermentation, his work was marred by the mysticism of the day, which called in the aid of supernatural agencies to explain what could not otherwise be fully comprehended.

In the two hundred and fifty years that have intervened between the death of van Helmont and the present day, alchemy became a more and more exact science and changed its name to chemistry, and a few striking names stand out of men who were able to take the new facts of chemistry and apply them to physiological uses. Of these one may mention Mayow, Lower, Boerhaave, Réaumur, Borelli, Spallanzani and Lavoisier. Mulder in Holland and Liebig in Germany bring us almost to the present time, and I think they may be said to share the honour of being regarded as the fathers of modern chemical physiology. This branch of science was first placed on a firm basis by Wöhler when he showed that organic compounds can be built out of their elements in the laboratory, and his first successful experiments in connection with the comparatively simple substance urea have been followed by numberless others, which have made organic chemistry the vast subject it is to-day.

Sir Michael Foster's book on the History of Physiology, from which I have already quoted, treats of the older workers who laid the foundations of our science, and whose names I have not done much more than barely mention. Those interested in the giants of the past should consult it. But what I propose to take up this morning is the work of those who have during more recent days been engaged in the later stages of the building. The edifice is far from completion even now. It is one of the charms of physiological endeavour that, as the older areas yield their secrets to the explorers, new ones are opened out which require equally careful investigation.

If even a superficial survey of modern physiological literature is taken, one is at once struck with the great preponderance of papers and books which have a chemical bearing. In this the

physiological journals of to-day contrast very markedly with those of thirty, twenty, or even ten years ago. The sister science of chemical pathology is making similar rapid strides. In some universities the importance of biological chemistry is recognised by the foundation of chairs which deal with that subject alone; and though in the United Kingdom, owing mainly to lack of funds, this aspect of the advance of science is not very evident, there are signs that the date cannot be far distant when every well-equipped university or university college will follow the example set us at many seats of learning on the Continent and at Liverpool.

With these introductory remarks let me now proceed to describe what appear to me to be the main features of chemical physiology at the present time.

The first point to which I shall direct your attention is the rapid way in which chemical physiology is becoming an exact science. Though it is less than twenty years since I began to teach physiology, I can remember perfectly well a time when those who devoted their work to the chemical side of the science might almost be counted on the fingers of one hand, and when chemists looked with scarcely veiled contempt on what was at that time called physiological chemistry; they stated that physiologists dealt with messes or impure materials, and therefore anything in the nature of correct knowledge was not possible. There was a good deal of truth in these statements, and if physiologists to-day cannot quite say that they have changed all that, they can at any rate assert with truth that they are changing it. This is due to a growing *rapprochement* between chemists and physiologists. Many of our younger physiologists now go through a thorough preliminary chemical training; and on the other hand there is a growing number of chemists—of whom Emil Fischer may be taken as a type—who are beginning to recognise the importance of a systematic study of substances of physiological interest. A very striking instance of this is seen in the progress of our knowledge of the carbohydrates, which has culminated in the actual synthesis of several members of the sugar group. Another instance is seen in the accurate information we now possess of the constitution of uric acid. When Miescher began his work on the chemical composition of the nuclei of cells, and separated from them the material he called nuclein, he little foresaw the wide practical application of his work. We now know that it is in the metabolism of cell-nuclei that we have to look for the oxidative formation of uric acid and other substances of the purine family. Already the chemical relationships of uric acid and nuclein have taught practical physicians some of the secrets that underlie the occurrence of gout and allied disorders.

With the time at my disposal, it would be impossible to discuss all the chemico-vital problems which the physiologists of the present day are attempting to solve, but there is one subject at which many of them are labouring which seems to me to be of supreme importance—I mean the chemical constitution of proteid or albuminous substances. Proteids are produced only in the living laboratory of plants and animals; proteid metabolism is the main chemical attribute of a living thing; proteid matter is the all-important material present in protoplasm. But in spite of the overwhelming importance of the subject, chemists and physiologists alike have far too long fought shy of attempting to unravel the constitution of the proteid molecule. This molecule is the most complex that is known; it always contains five, and often six, or even seven elements. The task of thoroughly understanding its composition is necessarily vast, and advance slow. But little by little the puzzle is being solved, and this final conquest of organic chemistry, when it does arrive, will furnish physiologists with new light on many of the dark places of physiological science.

The revival of the vitalistic conception in physiological work appears to me a retrograde step. To explain anything we are not fully able to understand in the light of physics and chemistry by labelling it as vital or something we can never hope to understand is a confession of ignorance, and, what is still more harmful, a bar to progress. It may be that there is a special force in living things that distinguishes them from the inorganic world. If this is so, the laws that regulate this force must be discovered and measured, and I have no doubt that those laws when discovered will be found to be as immutable and regular as the force of gravitation. I am, however, hopeful that the scientific workers of the future will discover that this so-called vital force is due to certain physical or chemical properties of living matter which have not yet been brought into line with the known chemical and physical laws that operate in the inorganic world, but which as our knowledge of chemistry and physics increases will ultimately be found to be subservient to such laws.

Let me take as an example the subject of osmosis. The laws which regulate this phenomenon through dead membranes are fairly well known and can be experimentally verified; but in the living body there is some other manifestation of force which operates in such a way as to neutralise the known force of osmosis. Is it necessary to suppose that this force is a new one? May it not rather be that our much vaunted knowledge of osmosis is not yet complete? It is quite easy to understand why a dead and a living membrane should behave differently in relation to substances that are passing through them. The molecules of the dead membrane are, comparatively speaking, passive and stable; the molecules in a membrane made of living cells are in a constant state of chemical integration and disintegration; they are the most unstable molecules we know. Is it to be expected that such molecules would allow water, or substances dissolved in water, to pass between them and remain entirely inactive? The probability appears to me to be all the other way; the substances passing, or attempting to pass, between the molecules will be called upon to participate in the chemical activities of the molecules themselves, and in the building up and breaking down of the compounds so formed there will be a transformation of chemical energy and a liberation of what looks like a new force. Before a physicist decides that his knowledge of osmosis is final, let him attempt to make a membrane of some material which is in a state of unstable chemical equilibrium, a state in some way comparable to what is called metabolism in living protoplasm. I cannot conceive that such a task is insuperable, and when accomplished, and the behaviour of such a membrane in an osmometer or dialyser is studied, I am convinced that we shall find that the laws of osmosis as formulated for such dead substances as we have hitherto used will be found to require revision.

Such an attitude in reference to vital problems appears to be infinitely preferable to that which too many adopt of passive content, saying the phenomenon is vital and there is an end of it.

When a scientific man says this or that vital phenomenon cannot be explained by the laws of chemistry and physics, and therefore must be regulated by laws of some other nature, he most unjustifiably assumes that the laws of chemistry and physics have all been discovered. He forgets, for instance, that such an important detail as the constitution of the proteid molecule has still to be made out.

The recent history of science gives an emphatic denial to such a supposition. All my listeners have within the last few years seen the discovery of the Röntgen rays and the modern development of wireless telegraphy. On the chemical side we have witnessed the discovery of new elements in the atmosphere and the introduction of an entirely new branch of chemistry called physical chemistry. With such examples ready to our hands, who can say what further discoveries will not shortly be made, even in such well-worked fields as chemistry and physics?

The mention of physical chemistry brings me to what I may term the second head of my discourse, the second striking characteristic of modern chemical physiology; this is the increasing importance which physiologists recognise in a study of inorganic chemistry. The materials of which our bodies are composed are mainly organic compounds, among which the proteids stand out as preeminently important; but everyone knows there are many substances of the mineral or inorganic kingdom present in addition. I need hardly mention the importance of water, of the oxygen of the air, and of salts like sodium chloride and calcium phosphate.

The new branch of inorganic chemistry called physical chemistry has given us entirely new ideas of the nature of solutions, and the fact that electrolytes in solution are broken up into their constituent ions is one of fundamental importance. One of the many physiological aspects of this subject is seen in a study of the action of mineral salts in solution on living organisms and parts of organisms. Many years ago Dr. Ringer showed that contractile tissues (heart, cilia, &c.) continue to manifest their activity in certain saline solutions. Howell goes so far as to say, and probably correctly say, that the cause of the rhythmical action of the heart is the presence of these inorganic substances in the blood or lymph which usually bathes it. The subject has more recently been taken up by Loeb and his colleagues at Chicago; they confirm Ringer's original statements, but interpret them now as ionic action. Contractile

tissues will not contract in pure solutions of non-electrolytes like sugar or albumin. But different contractile tissues differ in the nature of the ions which are their most favourable stimuli. An optimum salt solution is one in which stimulating ions, like those of sodium, are mixed with a certain small amount of those which like calcium restrain activity. Loeb considers that the ions act because they affect either the physical condition of the colloidal substances (proteid, &c.) in protoplasm or the rapidity of chemical processes.

Amœboid movement, ciliary movement, the contraction of muscle, cell division and karyokinesis all fall into the same category as being mainly dependent on the stimulating action of ions.

Loeb has even gone so far as to consider that the process of fertilisation is mainly ionic action; he denies that the nuclein of the male cell is essential, but asserts that all it does is to act as the stimulus in the due adjustment of the proportions of the surrounding ions, and supports this view by numerous experiments on ova in which without the presence of spermatozoa he has produced larvæ by merely altering the saline constituents and so the osmotic pressure of the fluid that surrounds them. Whether such a sweeping and almost revolutionary notion will stand the test of further verification must be left to the future; so also must the equally important idea that nervous impulses are to be mainly explained on an electrolytic basis. But whether or not all the details of such work will stand the test of time, the experiments I have briefly alluded to are sufficient to show the importance of physical chemistry to the physiologist, and they also form a useful commentary on what I was saying just now about vitalism. Such eminently vital phenomena as movement and fertilisation are to be explained in whole or in part as due to the physical action of inorganic substances. Are not such suggestions indications of the undesirability of postulating the existence of any special mystic vital force?

I have spoken up to this point of physical chemistry as a branch of inorganic chemistry; there are already indications of its importance also in relation to organic chemistry. Many eminent chemists consider that the future advance of organic chemistry will be on the new physical lines. It is impossible to forecast where this will lead us; suffice it to say that not only physiology, but also pathology, pharmacology and even therapeutics will receive new accessions to knowledge the importance of which will be enormous.

I have now briefly sketched what appear to me to be the two main features of the chemical physiology of to-day, and the two lines, organic and inorganic, along which I believe it will progress in the future.

Let me now press upon you the importance in physiology, as in all experimental sciences, of the necessity first of bold experimentation, and secondly of bold theorising from experimental data. Without experiment all theorising is futile; the discovery of gravitation would never have seen the light if laborious years of work had not convinced Newton that it could be deduced from his observations. The Darwinian theory was similarly based upon data and experiments which occupied the greater part of its author's lifetime to collect and perform. Pasteur in France and Virchow in Germany supply other instances of the same devotion to work which was followed by the promulgation of wide-sweeping generalisations.

And after all it is the general law which is the main object of research; isolated facts may be interesting and are often of value, but it is not until facts are correlated and the discoverers ascertain their inter-relationships that anything of epoch-making importance is given to the world.

It is, however, frequently the case that a thinker with keen insight can see the general law even before the facts upon which it rests are fully worked out. Often such bold theorisers are right, but even if they ultimately turn out to be wrong, or only partly right, they have given to their fellows some general idea on which to work; if the general idea is incorrect, it is important to prove it to be so in order to discover what is right later on. No one has ever seen an atom or a molecule, yet who can doubt that the atomic theory is the sheet anchor of chemistry? Mendeléeff formulated his periodic law before many of the elements were discovered; yet the accuracy of this great generalisation has been such that it has actually led to the discovery of some of the missing elements.

I purpose to illustrate these general remarks by a brief allusion to two typical sets of researches carried out during recent years in the region of chemical physiology. I do not pretend that either of them has the same overwhelming importance as the great discoveries I have alluded to, but I am inclined to think that one of them comes very near to that standard. The investigations in question are those of Ehrlich and of Pawlow. The work of Ehrlich mainly illustrates the useful part played by bold theorising, the work of Pawlow that played by the introduction of new and bold methods of experiment.

I will take Pawlow first. This energetic and original Russian physiologist has by his new methods succeeded in throwing an entirely new light on the processes of digestion. Ingeniously devised surgical operations have enabled him to obtain the various digestive juices in a state of absolute purity and in large quantity. Their composition and their actions on the various foodstuffs have thus been ascertained in a manner never before accomplished; an apparently unfailing resourcefulness in devising and adapting experimental methods has enabled him and his fellow workers to discover the paths of the various nerve impulses by which secretion in the alimentary canal is regulated and controlled. The importance of the psychical element in the process of digestion has been experimentally verified. If I were asked to point out what I considered to be the most important outcome of all this painstaking work, I should begin my answer by a number of negatives, and would say, not the discovery of the secretory nerves of the stomach or pancreas: not the correct analysis of the gastric juice, nor the fact that the intestinal juice has most useful digestive functions; all of these are discoveries of which anyone might have been rightly proud; but after all they are more or less isolated facts. The main thing that Pawlow has shown is that digestion is not a succession of isolated acts, but each one is related to its predecessor and to that which follows it; the process of digestion is thus a continuous whole; for example, the acidity of the gastric juice provides for a delivery of pancreatic juice in proper quantity into the intestine; the intestinal juice acts upon the pancreatic, and so enables the latter to perform its powerful actions. I am afraid this example, as I have tersely stated it, presents the subject rather inadequately, but it will serve to show what I mean. Further, the composition of the various juices is admirably adjusted to the needs of the organism; when there is much proteid to be digested, the proteolytic activity of the juices secreted is correspondingly high, and the same is true for the other constituents of the food. It is such general conclusions as these, the correlation of isolated facts leading to the formulation of the law that the digestive process is continuous in the sense I have indicated, and adapted to the needs of the work to be done, that constitute the great value of the work from the Russian laboratory. Work of this sort is sure to stimulate others to fill in the gaps and complete the picture, and already has borne fruit in this direction. It has, for instance, in Starling's hands led to the discovery of a chemical stimulus to pancreatic secretion. This is formed in the intestine as the result of the action of the gastric acid, and taken by the blood-stream to the pancreas. Whether this *secretin* as it is called may be one of a group of similar chemical stimuli which operate in other parts of the body has still to be found out.

The other series of researches to which I referred are those of Ehrlich and his colleagues and followers on the subject of immunity. This subject is one of such importance to every one of us that I am inclined to place the discovery on a level with those great discoveries of natural laws to which I alluded at the outset of this portion of my Address. I hesitate to do so yet because many of the details of the theory still await verification. But up to the present all is working in that direction, and Ehrlich's ideas illustrate the value of bold theorising in the hands of clear-sighted and far-seeing individuals.

But when I say that the doctrine is bold, I do not mean to infer that the experimental facts are scanty; they are just the reverse. But in the same way that a chemist has never seen an atom, and yet he believes atoms exist, so no one has yet ever seen a toxin or antitoxin in a state of purity, and yet we know they exist, and this knowledge promises to be of incalculable benefit to suffering humanity.

It may not be uninteresting to state briefly, for the benefit of those to whom the subject is new, the main facts and an outline of the theory which is based upon them.

We are all aware that one attack of many infective maladies protects us against another attack of the same disease. The person is said to be *immune* either partially or completely against that disease. Vaccination produces in a patient an

attack of cow-pox or vaccinia. This disease is related to small-pox, and some still hold that it is small-pox modified and rendered less malignant by passing through the body of a calf. At any rate, an attack of vaccinia renders a person immune to small-pox, or variola, for a certain number of years. Vaccination is an instance of what is called *protective inoculation*, which is now practised with more or less success in reference to other diseases like plague and typhoid fever. The study of immunity has also rendered possible what may be called *curative inoculation*, or the injection of antitoxic material as a cure for diphtheria, tetanus, snake poisoning, &c.

The power the blood possesses of slaying bacteria was first discovered when the effort was made to grow various kinds of bacteria in it; it was looked upon as probable that blood would prove a suitable soil or medium for this purpose. It was found in some instances to have exactly the opposite effect. The chemical characters of the substances which kill the bacteria are not fully known; indeed, the same is true for most of the substances we have to speak of in this connection. Absence of knowledge on this particular point has not, however, prevented important discoveries from being made.

So far as is known at present, the substances in question are proteid in nature. The bactericidal powers of blood are destroyed by heating it for an hour to 56° C. Whether the substances are enzymes is a disputed point. So also is the question whether they are derived from the leucocytes; the balance of evidence appears to me to be in favour of this view in many cases at any rate, and phagocytosis becomes more intelligible if this view is accepted. The substances, whatever be their source or their chemical nature, are sometimes called alexins, but the more usual name now applied to them is that of *bacteriolysins*.

Closely allied to the bactericidal power of blood, or blood-serum, is its globulicidal power. By this one means that the blood-serum of one animal has the power of dissolving the red blood-corpuscles of another species. If the serum of one animal is injected into the blood-stream of an animal of another species, the result is a destruction of its red corpuscles, which may be so excessive as to lead to the passing of the liberated hæmoglobin into the urine (hæmoglobinuria). The substance or substances in the serum that possess this property are called *haemolysins*, and though there is some doubt whether bacteriolysins and hæmolysins are absolutely identical, there is no doubt that they are closely related substances.

Another interesting chemical point in this connection is the fact that the bactericidal power of the blood is closely related to its alkalinity. Increase of alkalinity means increase of bactericidal power. Venous blood contains more diffusible alkali than arterial blood and is more bactericidal; dropsical effusions are more alkaline than normal lymph and kill bacteria more easily. In a condition like diabetes, when the blood is less alkaline than it should be, the susceptibility to infectious diseases is increased. Alkalinity is probably beneficial because it favours those oxidative processes in the cells of the body which are so essential for the maintenance of healthy life.

Normal blood possesses a certain amount of substances which are inimical to the life of our bacterial foes. But suppose a person gets run down; everyone knows he is then liable to "catch anything." This coincides with a diminution in the bactericidal power of his blood. But even a perfectly healthy person has not an unlimited supply of bacteriolysin, and if the bacteria are sufficiently numerous he will fall a victim to the disease they produce. Here, however, comes in the remarkable part of the defence. In the struggle he will produce more and more bacteriolysin, and if he gets well it means that the bacteria are finally vanquished, and his blood remains rich in the particular bacteriolysin he has produced, and so will render him immune to further attacks from that particular species of bacterium. Every bacterium seems to cause the development of a specific bacteriolysin.

Immunity can more conveniently be produced gradually in animals, and this applies, not only to the bacteria, but also to the toxins they form. If, for instance, the bacilli which produce diphtheria are grown in a suitable medium, they produce the diphtheria poison, or toxin, much in the same way that yeast-cells will produce alcohol when grown in a solution of sugar. Diphtheria toxin is associated with a proteose, as is also the case with the poison of snake venom. If a certain small dose called a "lethal dose" is injected into a guinea-pig, the result is death. But if the guinea-pig receives a smaller dose it will recover; a few days after it will stand a rather larger dose; and this may be continued until after many successive gradually increasing doses it will finally stand an amount equal to many lethal doses without any ill effects. The gradual introduction of the toxin has called forth the production of an antitoxin. If this is done in the horse instead of the guinea-pig the production of antitoxin is still more marked, and the serum obtained from the blood of an immunised horse may be used for injecting into human beings suffering from diphtheria, and rapidly cures the disease. The two actions of the blood, antitoxic and antibacterial, are frequently associated, but may be entirely distinct.

The antitoxin is also a proteid probably of the nature of a globulin; at any rate, it is a proteid of larger molecular weight than a proteose. This suggests a practical point. In the case of snake-bite the poison gets into the blood rapidly owing to the comparative ease with which it diffuses, and so it is quickly carried all over the body. In treatment with the antitoxin or antivenin, speed is everything if life is to be saved; injection of this material under the skin is not much good, for the diffusion into the blood is too slow. It should be injected straight away into a blood-vessel.

There is no doubt that in these cases the antitoxin neutralises the toxin much in the same way that an acid neutralises an alkali. If the toxin and antitoxin are mixed in a test-tube and time allowed for the interaction to occur, the result is an innocuous mixture. The toxin, however, is merely neutralised, not destroyed; for if the mixture in the test-tube is heated to 68° C. the antitoxin is coagulated and destroyed and the toxin remains as poisonous as ever.

Immunity is distinguished into *active* and *passive*. Active immunity is produced by the development of protective substances in the body; passive immunity by the injection of a protective serum. Of the two the former is the more permanent.

Ricin, the poisonous proteid of castor-oil seeds, and *abrin*, that of the Jequirity bean, also produce when gradually given to animals an immunity, due to the production of antiricin and antiabrin respectively.

Ehrlich's hypothesis to explain such facts is usually spoken of as the *side-chain theory* of immunity. He considers that the toxins are capable of uniting with the protoplasm of living cells by possessing groups of atoms like those by which nutritive proteids are united to cells during normal assimilation. He terms these *haptophor* groups, and the groups to which these are attached in the cells he terms *receptor* groups. The introduction of a toxin stimulates an excessive production of receptors, which are finally thrown out into the circulation, and the free circulating receptors constitute the antitoxin. The comparison of the process to assimilation is justified by the fact that non-toxic substances like milk introduced gradually by successive doses into the blood-stream cause the formation of anti-substances capable of coagulating them.

Up to this point I have spoken only of the blood, but month by month workers are bringing forward evidence to show that other cells of the body may by similar measures be rendered capable of producing a corresponding protective mechanism.

One further development of the theory I must mention. At least two different substances are necessary to render a serum bactericidal or globulicidal. The bacteriolysin or hæmolysin consists of these two substances. One of these is called the *immune body*, the other the *complement*. We may illustrate the use of these terms by an example. The repeated injection of the blood of one animal (*e.g.* the goat) into the blood of another animal (*e.g.* a sheep) after a time renders the latter animal immune to further injections, and at the same time causes the production of a serum which dissolves readily the red blood-corpuscles of the first animal. The sheep's serum is thus hæmolytic towards goat's blood-corpuscles. This power is destroyed by heating to 56° C. for half an hour, but returns when fresh goat's serum is added. The specific immunising substance formed in the sheep is called the immune body; the ferment-like substance destroyed by heat is the complement. The latter is not specific, since it is furnished by the blood of non-immunised animals, but it is nevertheless essential for hæmolysis. Ehrlich believes that the immune body has two side groups—one which connects with the receptor of the red corpuscles and one which unites with the haptophor group of the complement, and thus renders possible the ferment-like action of the complement on the red corpuscles. Various antibacterial serums which have not been

the success in treating disease they were expected to be are probably too poor in complement, though they may contain plenty of the immune body.

Quite distinct from the bactericidal, globulicidal and antitoxic properties of blood is its agglutinating action. This is another result of infection with many kinds of bacteria or their toxins. The blood acquires the property of rendering immobile and clumping together the specific bacteria used in the infection. The test applied to the blood in cases of typhoid fever, and generally called Widal's reaction, depends on this fact.

The substances that produce this effect are called *agglutinins.* They also are probably proteid-like in nature, but are more resistant to heat than the lysins. Prolonged heating to over 60° C. is necessary to destroy their activity.

Lastly, we come to a question which more directly appeals to the physiologist than the preceding, because experiments in relation to immunity have furnished us with what has hitherto been lacking, a means of distinguishing human blood from the blood of other animals.

The discovery was made by Tchistovitch (1899), and his original experiment was as follows :—Rabbits, dogs, goats and guinea-pigs were inoculated with eel-serum, which is toxic ; he thereby obtained from these animals an antitoxic serum. But the serum was not only antitoxic, but produced a precipitate when added to eel-serum, but not when added to the serum of any other animal. In other words, not only has a specific antitoxin been produced, but also a specific *precipitin.* Numerous observers have since found that this is a general rule throughout the animal kingdom, including man. If, for instance, a rabbit is treated with human blood, the serum ultimately obtained from the rabbit contains a specific precipitin for human blood ; that is to say, a precipitate is formed on adding such a rabbit's serum to human blood, but not when added to the blood of any other animal.[1] The great value of the test is its delicacy ; it will detect the specific blood when it is greatly diluted, after it has been dried for weeks, or even when it is mixed with the blood of other animals.

I have entered into this subject at some length, because it so admirably illustrates the kind of research which is now in progress ; it is also of interest to others than mere physiologists. I have not by any means exhausted the subject, but for fear I may exhaust my audience let me hasten to a conclusion. I began by eulogising the progress of the branch of science on which I have elected to speak to you. Let me conclude with a word of warning on the danger of over-specialisation. The ultra-specialist is apt to become narrow, to confine himself so closely to his own groove that he forgets to notice what is occurring in the parallel and intercrossing grooves of others. But those who devote themselves to the chemical side of physiology run but little danger of this evil. The subject cannot be studied apart from other branches of physiology, so closely are both branches and roots intertwined. As an illustration of this, may I be permitted to speak of some of my own work ? During the past few years the energies of my laboratory have been devoted to investigations on the chemical side of nervous activity, and I have had the advantage of cooperating to this end with a number of investigators, of whom I may particularly mention Dr. Mott and Dr. T. G. Brodie. But we soon found that any narrow investigation of the chemical properties of nervous matter and the changes this undergoes during life and after death was impossible. Our work extended in a pathological direction so as to investigate the matter in the brains of those suffering from nervous disease ; it extended in a histological direction so as to determine the chemical meaning of various staining reactions presented by normal and abnormal structures in the brain and spinal cord ; it extended in an experimental direction in the elucidation of the phenomena of fatigue, and to ascertain whether there was any difference in medullated and non-medullated nerve fibres in this respect ; it extended into what one may call a pharmacological direction in the investigation of the action of the poisonous products of the breakdown of nervous tissues. I think I have said enough to show you how intimate are the connections of the chemical with the other aspects of physiology, and although I have given you but one instance, that which is freshest to my mind, the same could be said for almost any other well-planned piece of research work of a bio-chemical nature.

[1] There may be a slight reaction with the blood of allied animals ; for instance, with monkey's blood in the case of man.

We have now before us the real work of the Section, the reading, hearing and seeing the researches which will be brought forward by members of the Association, and I must, in thanking you for your attention, apologise for the length of time I have kept you from these more important matters.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IT is recommended by Mr. Herbert Welsh, of Philadelphia, who was largely instrumental in raising the Wilson endowment fund, value 100,000 dollars, of the Washington and Lee University, that a fund of 500,000 dollars be raised to endow a scientific and technical school for the University.

THE papers read at the conference of science teachers held at the Hartley University College, Southampton, to which attention was directed in our issue of June 19, 1902, have now been published in book form. The title of the little volume is "Science Teaching and Nature Study." Copies may be obtained from Mr. H. M. Gilbert, Above Bar, Southampton, price 6*d*. each.

THE following courses of lectures on advanced physiology are announced for delivery in the physiological laboratory at the buildings of the University of London during the coming term :—(*a*) "On the Sources of Animal Energy," by Prof. E. H. Starling, on Tuesdays, October 14, 21, 28, November 4, 11, 18, 25, December 2, at 5 p.m. ; (*b*) "On Animal Heat and Respiration," by Dr. M. S. Pembrey, on Wednesdays, October 15, 22, 29, November 5, 12, 19, 26, December 3, at 5 p.m. The lectures, admission to which is free, are addressed to advanced students, and are arranged to meet the requirements of candidates for honours in physiology at the University. Cards of admission may be obtained on application to the Academic Registrar, at the University Buildings, South Kensington, S.W.

SCIENTIFIC SERIALS.

Journal of Botany, September.—Under the title of "Alabastra diversa," Mr. Spencer le M. Moore continues his account of new plants. *Amphoranthus spinosus*, from Damaraland, furnishes a new genus of the suborder Cæsalpinieæ, approximating to the existing genus Cordyla. Five new species are added to the Acanthaceæ. A note by the same writer refers to the plant which, under the name of *Haemacanthus coccineus*, was described in a previous number of the *Journal* as a new genus ; there is some possibility of this proving to be identical with the plant named *Satanocrater coccineus* by Dr. Lindau.—Dr. Rendle describes two new varieties of orchids from China, and a new species of Burmannia from the same country. The latter is figured along with Amphoranthus.—Two papers deal with the genus Hieracium ; in the first, Mr. H. J. Riddelsdell gives a list of Welsh Hieracia ; in the second, Mr. F. N. Williams, in the course of his remarks on the "Salient Features in Hieracium," alludes to the difference between the characters emphasised by Scandinavian and Continental botanists, and points out the importance of the hairs, the structure of the receptacle and the stem branching as distinguishing morphological features.—Messrs. R. E. and F. Cundall contribute a list of Glamorganshire plants which furnishes a supplement to that published recently by Messrs. Marshall and Shoolbred.—The article entitled "Botany in England a Century Ago" gives the impressions of Dr. H. A. Noehden formed during his visit to this country in the year 1799.

The American Journal of Science, September.—The relationships of some American and Old World birches, by M. L. Fernald.—On the fertile fronds of Crossotheca and Myriotheca, and on the spores of other Carboniferous ferns from Mazon Creek, Illinois, by E. H. Sellards.—On the validity of *Idiophyllum rotundiflorum*, Lesquereux, a fossil plant from the Coal-measures of Mazon Creek, Illinois, by E. H. Sellards. It

is shown that the species *Idiophyllum rotundiflorum* is a synonym of *Neuropteris rarinervis*, and that the genus Idiophyllum has no status in fossil botany.—The precipitation of ammonium vanadate by ammonium choride, by F. A. Gooch and R. D. Gilbert. Previous work on the separation of vanadium as ammonium metavanadate by means of ammonium chloride having led to contradictory results, the method has been exhaustively re-examined, with the result that under suitable conditions, easily realised experimentally, the determination by Gibbs's method is accurate.—Some additions to the alunite-jarosite group of minerals, by W. F. Hillebrand and S. L. Penfield.—The Niagara limestones of Hamilton County, Indiana, by Edward M. Kindle.—On the velocity and the structure of the nucleus, by C. Barus.—Note on corundum and a graphitic essonite from Barkhampstead, Connecticut, by B. K. Emerson.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 22.—M. Bouquet de la Grye in the chair.—The president announced to the Academy the loss it had sustained by the death of M. Damour.—The extension of Fermat's principle on the economy of time to the relative movement of light in a transparent homogeneous body subject to a rapid translation, by M. J. Boussinesq. It is shown that the principle of least time as enunciated by Fermat applies to the case of a body subjected to a rapid translatory motion. Polarisation is also unaffected.—The enclosures in the andesites from Mont Pelée, by M. A. Lacroix. The enclosures contain a greenish or yellowish-grey rock of a microlitic character; the mineralogical composition is always the same qualitatively, but the proportion of the elements varies considerably. The most complete type contains plagioclases, hypersthene, augite, titanomagnetite, hornblende and olivine. These enclosures are not fragments of solid rock torn off from the depths of the volcano, there being abundant evidence that they have been formed in place. They greatly resemble certain nodules of hypersthene-andesite from the last eruption of Santorin.—Spectral researches on the rotation of the planet Uranus, by M. H. Deslandres. The first researches on the rotation of the planets have been made by simply measuring the movement of certain well-defined points; if the image is uniform and without detail, this method fails. On account of the small apparent diameter and feeble lustre of Neptune and Uranus, their time of rotation has hitherto remained undetermined. A new mode of attacking this problem is by applying the Döppler-Fizeau principle. This was first applied successfully to the Sun in 1889, to Jupiter and Saturn in 1895, and to Venus in 1900. The same method in a modified form has now been applied to Uranus, with the result that it is very probable that this planet turns in a retrograde sense, like its satellites. To obtain more definite measurements, further researches must be carried out in observatories nearer the equator, with more powerful instruments and in a very calm atmosphere, and for a period of twenty-one years. Encouraging results have also been obtained by the application of the same method to the planet Neptune.—On the combinations of silicon with cobalt, and on a new silicide of this metal, by M. P. Lebeau. When cobalt is heated in the presence of an excess of fused silicon, or when a mixture of silicide of copper, cobalt and silicon is submitted to the temperature of the electric furnace, a well-crystallised cobalt silicide of the composition Si_2Co is formed, the physical properties and chemical reactions of which are given in detail. Cobalt thus forms three definite crystalline compounds with silicon, having the formulæ $SiCo_2$, SiCo and Si_2Co, these compounds forming a series in all respects comparable with the silicides of iron.—On the calorific power of coal, by M. Goutal. By an examination of 600 specimens of coal of different kinds, the calorific value (P) is found to be given, with an approximation of 1 per cent., by the formula $P = 82\ C + a\ V$, in which C is the percentage of ash-free coke, V the volatile matter, and a a coefficient, a curve for the determination of which is given in the paper. The error may amount to 2 per cent. of the calorific value in the case of anthracite and some lignites.—On the existence of stable yeast forms in some moulds, by M. G. Odin.—On a modification produced in *Scopolia carnolica* following its grafting on the tomato, by M. Lucien Daniel.

NEW SOUTH WALES.

Royal Society, August 6.—Prof. Warren, president, in the chair.—On the mitigation of floods in the Hunter River, by Mr. J. H. Maiden. The paper discusses the subject from the point of view of the forester.

MENDEL'S THEORY OF HEREDITY.

Mendel's Principles of Heredity: a Defence. By W. Bateson, M.A., F.R.S. With a Translation of Mendel's Original Papers on Hybridisation. Pp. xiv + 212. (Cambridge: University Press, 1902.) Price 4s. net.

Reports to the Evolution Committee of the Royal Society. Report I. Experiments undertaken by W. Bateson, F.R.S., and Miss E. R. Saunders. Pp. 160. (London: Harrison, 1902.) Price 10s.

THERE can be no question of the importance, in reference to evolutionary theory, of a proper comprehension of the principles of heredity. Many attempts towards a solution of the problem have been made, but to none of them has it been possible hitherto to give more than a provisional approval. While the nature of this process remains unknown, the fabric of evolution cannot be regarded as in any sense complete. It seems certain that at present the question may be most hopefully approached from the statistical side, and to the labours of Galton and of Pearson we owe the enunciation of a law which gives quantitative expression to many of the observed facts. But about two years ago the discovery was made that Gregor Mendel, sometime Abbot of Brünn, had long since, in the seclusion of his cloister, devised and carried through a very remarkable series of experiments in cross-fertilisation; and had on them based a theory which bids fair, if its truth can be established, to put the whole subject of heredity on an entirely new footing.

After more than thirty years of neglect, the Mendelian theory has found an energetic champion in Mr. Bateson, to whose lucid and exhaustive exposition of the doctrine in the two volumes before us students of the problem will naturally turn. Here we can only state in very briefest outline some of the main conclusions to which Mendel was led. In the instances (of pea-plants) selected by him for experiment, it was found that when two plants, differing in a given feature, were crossed, the hybrid offspring invariably exhibited one of the parental characters (called by Mendel the "dominant") to the entire or partial exclusion of the other (called "recessive"). After self-fertilisation, each hybrid produced offspring in which the two antagonistic parental characters (Bateson's "allelomorphs"), dominant and recessive, appeared in a ratio closely approximating on an average to 3 : 1. Further experiment showed that while the recessive minority henceforth bred true, the other class consisted of one-third genuine dominants also breeding true, and two-thirds "cross-breds" (Bateson's "heterozygotes"), which latter on self-fertilisation again gave the old ratio of 3 : 1, and so on. When plants differing in several characters instead of one only were taken, *mutatis mutandis* the same law was found to hold good. From these and other experiments, ingeniously devised and giving wonderfully accordant results, Mendel was led to formulate the hypothesis of the numerical equality in kinds, and purity in respect of given characters, of the gametes produced by any zygote, whatever the composition of the latter. The consequences of the acceptance of this view would undoubtedly be far-reaching, and Mr. Bateson does well, in reprinting a translation of Mendel's original papers and also in recording the illustrative experiments made by himself and Miss E. R. Saunders, to trace out in considerable detail the main lines of speculation thus laid open.

The chief issue between the Mendelian and Galtonian conceptions is the question of "ancestral" heredity; and in disallowing the latter Mr. Bateson is pitting himself against a formidable triumvirate. Prof. Weldon has discussed Mendel's results from this point of view in a critical, but, as it seems to us, not unfriendly spirit. Much may be conceded to the zeal of an advocate, but we regret certain personalities in Mr. Bateson's "Defence." An impartial judge, after hearing the able statements of counsel, would probably desire to adjourn the case for the production of further evidence.

On p. 71 of the first-named work, *Abab* should read $Ab+ab$, and similarly *aBab* should be $aB+ab$. Giltay's name appears in the bibliography as "Gitay."

F. A. D.

LIGHTNING ARRESTORS IN ELECTRICAL ENGINEERING.

Die Schutzvorrichtungen der Starkstromtechnik gegen atmosphärische Entladungen. By Dr. Gustav Benischke. (Brunswick: Friedr. Vieweg und Sohn.)

IT is customary in Germany to divide electrical engineering into two parts, the "Starkstrom" and "Schwachstrom"—the "strong" and "weak" current branches. This book is the first issue of a series, edited by Dr. Benischke, each issue to be complete in itself and to deal with some application of the industry. The first issue treats of the means adopted in the "strong current" branch, *i.e.* electric lighting and power, for protection against atmospheric electrical discharges With overhead lines, especially overhead power-transmission lines, this subject is one of great importance, and is also one upon which very little is known with certainty. It is interesting to find that the author, on the first page, gives it as his opinion that it is impossible to protect a line against the effects of being directly struck by lightning. In such a case a destruction of the insulation is bound to take place. It is well that electrical engineers should understand this, and be clear in their own minds that the so-called lightning arrestors at present on the market afford no protection here. Fortunately, such cases are very rare. Protection is afforded, according to Dr. Benischke, by lightning arrestors against the weaker side discharges which accompany the main lightning flash, also against spark discharges due to the static charges which the overhead conductors assume as the result of dust, snow, &c., and against induced discharges caused by atmospheric electrical disturbances in the neighbourhood.

The book contains a very clear and concise description of the various forms of lightning arrestors at present in use. Nearly all of them consist of spark gaps placed with one side of the gap connected to the conductor and the other side to earth. Should, therefore, at any time the conductor become charged to a high potential, a

spark is formed across the gap and the charge is thus conducted to earth. As now the electromotive force required to maintain an arc is much less than that required to start it across a gap, the arc is maintained by the ordinary voltage of the system, and has to be put out by some other means. Upon the methods adopted to do this Dr. Benischke bases his classification of the various arrestors as follows:—(1) An arc is not allowed to form by reason of the dividing up and cooling of the spark; (2) arc broken mechanically; (3) arc broken by a magnetic blow out; (4) arc broken by its own magnetic and thermal action; and (5) arrangements containing a large resistance in the earth connection.

This classification is all very well, but in our opinion does not give one a proper standpoint from which to judge of the value of the protection afforded.

Recent investigations have shown that the formation of an arc in the circuit of an underground cable is, in certain circumstances, attended with very grave danger. An arc in such a circuit, between horns, as, *e.g.*, in the Siemen's or the Allgemeine Elektricitäts Gesellschaft's arrestors, whether it is blown out by a magnet or by its own action on itself or other means, is very liable to produce those very rises in potential which it is the object of the arrestors to obviate. This very important consideration is not mentioned by the author. That, however, it is true is borne out by the fact that, in many English alternating-current high-tension stations, originally fitted up with spark-gap arrestors, their use has been attended with such bad results that they have been given up. Even if such so-called arrestors are scientifically good, it is very questionable if they can be made of practical service for high-tension systems by reason of their inherent want of sensitiveness. In support of this contention it may be mentioned that on p. 32 the author gives as an example of great sensitiveness the adjustment of the gap so that it will go across at double the working voltage. We are very certain, however, that there are very few high-tension underground cable systems which have such a large factor of safety. In, for example, a 5000- or 6000-volt system which has been running for some time, a rise of but 2000 or 3000 volts above the working pressure is generally sufficient to break the insulation down somewhere. In purely overhead lines the case is somewhat different, as it is very much easier here to make the insulation with a much larger safety factor.

In our opinion the proper arrestor for high-potential lines has yet to be designed. It must be so adaptable to the circuit on which it is placed that by its action no danger of rises of potential due to it can occur. By proper adjustment of its dimensions to the electrical constants of the circuit this can, perhaps, be arranged.

The arrestors classified by the author under No. 5 are, in our opinion, the most hopeful. In places like South Africa, where static charges are of constant occurrence, this form is the only one that has given any good result, on, of course, low-tension circuits. Their development for high tension is, however, a thing of the future, and has to cope with many difficulties, some of which are indicated in the book by the author.

Dr. Benischke's book is to be welcomed as a valuable contribution to a subject to which as yet so little attention has been paid. C. C. G.

OUR BOOK SHELF.

Catalogue of Scientific Papers (1800–1883), *Supplementary Volume.* Compiled by the Royal Society of London. Vol. xii. Pp. xxxii + 807. (London: C. J. Clay and Sons, 1902.)

The readers of Nature must be so familiar with the "Royal Society Catalogue" that it is needless to give any description of it; suffice it to say that when the work for the decade 1874–1883, printed in vols. ix. to xi., was in progress, it was found that a considerable number of periodicals had been omitted, many of which contained valuable papers. As stated in the preface to vol. ix., the President and Council contemplated the publication of a supplementary volume which should contain the most important papers that appeared between 1800 and 1883 in periodicals not hitherto catalogued.

A preliminary list of the omitted serials was made, and after a careful sifting it was found that 355 remained to be dealt with, the titles and abbreviations of which occupy twenty-six pages of the volume. These were catalogued in the same way as the previous portion of the work, but when the matter was prepared for the press it was evident that the amount to be printed was much greater than had been anticipated; the committee therefore decided that references to abstracts of papers that had appeared in previous volumes should be excluded, that all references to abstracts should be excluded except in the cases of papers in some other language than English, French, German, Italian or Latin, abstracts of which had been published in one of these languages, and in such a case reference was to be made to only one abstract. The effect of this curtailment was to reduce the work to about 800 pages.

The papers of each author are numbered as in the previous volumes; it must be noticed, however, that these numbers no longer represent the chronological order of publication.

Great care has been taken to ensure accuracy in the references, and many corrections of errors discovered in previous volumes have been made. Much credit is due to Miss Chambers and Miss Bremner and the ladies working under them, and also to the late Mr. George Griffith, who acted as editor.

The Early Life of the Young Cuckoo. By W. P. Westell. Pp. 26; illustrated. (London: Burleigh, 1902.) Price 1*s.* net.

In this little volume the author gives an account of the observations made by Mr. J. Craig, of Ayrshire, during the summer of 1899, as to the manner in which young cuckoos eject the other occupants of the nest in which they happen to have been hatched. Two of the photographs illustrating the work have appeared previously in the *Amateur Photographer* of November 28, 1901, in connection with a lecture by Mr. J. P. Millar; and it would perhaps have been better if the author had definitely informed his readers of this fact instead of merely stating that Mr. Craig's "photographs and observations have by this time been heard of throughout the ornithological world."

Since Mr. Craig's observations have not been previously referred to in Nature, they may be briefly noticed on the present occasion. At the commencement of June, 1899, Mr. Craig found a titlark's or meadow-pipit's nest containing five eggs, two of which were those of cuckoos. One of the titlark's eggs was broken in order to ascertain how long it had been brooded. In due course two young cuckoos were hatched out, one of the titlark's eggs being by this time broken and the other missing. One cuckoo soon succeeded in ejecting its fellow by carrying it on its back to the edge of the nest and tilting it over in the manner shown in the illustrations. The same process

was repeated when the ejected cuckoo, together with a young titlark, was returned to the nest. Other experiments of a similar nature were made subsequently with nestling buntings. The volume closes with a few general, and by no means original, notes on the life-history of the cuckoo. We are afraid that we cannot congratulate either Mr. Craig or the author on the theory advanced to account for the peculiar breeding-habits of the cuckoo. It is argued that if the bird laid a clutch of eggs in the usual manner the offspring would quarrel among themselves owing to their aggressive habits, the author of this theory forgetting that the disposition in question in the young is doubtless correlated with the present laying habit of the parent.

R. L.

Physics: a Text-book for Secondary Schools. By Prof. Frederick Slate. Pp. xxi + 414. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 6*s*.

THIS book is intended for young people from sixteen to eighteen years of age, and consequently deals with physics of an elementary standard. It is for use in the class-room rather than in the laboratory, and details of practical work have been omitted; whilst considerable stress is laid on ample illustration by means of lecture experiments. There are some diagrams, but no pictures of apparatus or phenomena; these the student is to draw for himself from what he sees. Much of the text is written in a spirit of suggestion or question, with the view of making the student think and reason for himself. In the first section of the book there is very little about kinetics, and ideas concerning force are gained from weight. Newton's laws are not stated formally, and work is not discussed until late in the section on heat.

Altogether we think the standard is very elementary, and it is an open question whether students of the ages seventeen to eighteen would not profit more by a rather deeper study of one or two branches of physics in place of this wide review of the whole subject. This, however, must be left to the individual teacher; some will certainly be delighted with this book, others, we feel sure, will prefer to treat the subject quite differently. S. S.

L'Électricité (déduite de l'Expérience et ramenée au Principe des Travaux virtuels). By M. E. Carvallo. Pp. 91. (Paris: C. Naud.) Price 2 francs.

Les Phénomènes électriques chez les Êtres vivants. By M. Mendelssohn. Pp. 99. (Paris: C. Naud.) Price 2 francs.

BOTH these volumes belong to the valuable "Scientia" series of short monographs upon important scientific topics.

M. Carvallo's book contains a concise mathematical treatment of electrical principles based upon the theories of Helmholtz and Maxwell and the principles of virtual work.

The second book contains a complete discussion of electrical phenomena observed in the muscles, nerves, skin, glands, nerve-centres and sense-organs. Separate chapters are also devoted to electrical fish, to the phenomena observed in certain forms of vegetation and to a historical review of the entire subject.

Elementary Chemical Analysis. Distinguishing Tables and Tests. By Prof. P. Carmody. Pp. v + 35. (Trinidad: D. Adamson and Co., 1902.) Price 2*s*. 6*d*.

IN those laboratories where a course of qualitative analysis is the plan adopted to give a knowledge of practical chemistry, these tables may prove useful. The reactions for the metals and acids are arranged in a tabular form, and by means of the tables the student learns, not only the ordinary methods of separation for the metals, but also their other distinctive tests.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"The Primrose and Darwinism."

I DESIRE to make a short reply in answer to two or three of your reviewer's criticisms on "The Primrose and Darwinism," and on its author, which appeared in your issue of August 28. "We do not propose," to adopt the words of your reviewer, "to go through the whole review, but to discuss one or two points and to leave your readers to judge of the remainder."

My first and chiefest point is in reference to the charge which the reviewer makes in the following statement (p. 411):—"The only point which is worthy of notice" (relative to the cleistogamic flowers) "is a quotation (Prim. and Dar., p. 191) from Darwin's 'Form of Flowers,' which has several copyist's mistakes, and, moreover, contains interpolated words which do not occur in the original, the whole being within inverted commas. It is this sort of treatment of Darwin's text that makes it almost impossible to read the 'Field Naturalist.'"

I give here an exact copy of Darwin's paragraph from "Form of Flowers," p. 323, and an exact copy both of words and inverted commas of my own comments on Darwin's statement. It will be evident to every reader that Darwin's own observations are always marked off by inverted commas, and that my own comments are not included within the commas. Your reviewer seems to have read my comment with exceeding carelessness.

Darwin's Text.	*My own comment.*
"The most singular fact about the present species is that long-styled cleistogamic flowers are produced by the long-styled plants, and mid-styled as well as short-styled cleistogamic flowers by the other two forms; so that there are three kinds of cleistogamic and three kinds of perfect flowers produced by this one species! Most of the hetero-styled species of Oxalis are more or less sterile, many absolutely so, if illegitimately fertilised with their own form pollen. It is therefore probable that the pollen of the cleistogamic flowers has been modified in power, so as to act on their own stigmas, for they yield an abundance of seeds" (p. 323 of last edition, 1892).	But in *Oxalis Sensitiva* "the long-styled cleistogamic flowers are produced by long-styled plants; the mid-styled as well as the short-styled cleistogamic flowers are produced respectively by the other two forms; so that there are three kinds of cleistogamic and three kinds of perfect flowers produced by this one species" (F. Fl., p. 323). Now, as Darwin, from his *net experiments*, concluded that "most of the hetero-styled species of *Oxalis* are more or less sterile, many absolutely so, if illegitimately fertilised with their own form pollen" (F. Fl., p. 323), he had in some way to account for this extreme contradiction in results between the naturally abundant fertility of these cleistogamic flowers, and his own results, which we have given above, of *Lythrum Salicaria*, under the unnatural method of experimenting with his net. Under this difficulty, Darwin suggests, "it is probable that the pollen of the cleistogamic flowers has been *modified* in power, so as to act on their stigmas, for they yield an abundance of seed" (F. Fl., p. 323. The italics are ours). (Prim. and Dar., p. 191.)

Again the reviewer states that the "Field Naturalist's" sentence (p. 11):—"To attribute the capacity for fertilisation in the unprotected flowers to the bees is perfectly gratuitous, as the flowers under the net (when bees were excluded) 'when they touched the net and the wind blew' produced seeds without any cross-fertilisation"—contains, in the words 'when they touched the net and the wind blew,' an "incorrect quotation" (p. 409).

Darwin's words are:—	*My quotation.*
"Salvia tenori. Quite sterile; but two or three flowers on the summits of three of the spikes, which touched the net when the wind blew, produced a few seeds" (Cr. and S.F., p. 362).	*Salvia tenori* under the net, Darwin tells us, "was quite sterile; but two or three flowers on the summit of the spikes, *which touched the net when the wind blew*, produced a few seeds" (Cr. and S.F., p. 362. The italics are ours). (Prim. and Dar., p. 11.)

The quotation is word for word from Darwin in the italicised words; yet the reviewer takes no notice of this, but produces a merely shortened form a few lines below, and which though shortened conveys exactly the same sense, and calls it "an incorrect quotation"!

One more charge of this kind of your reviewer scarcely needs being noticed. But I notice it in order to avoid any misinterpretation if I passed it over. The charge is one in reference to *Sarothamnus scoparius*. Darwin states concerning it (Cr. and S.F., p. 360):—"Extremely sterile when the flowers are neither

visited by bees, nor disturbed by being beaten by the wind against the surrounding net." The reviewer says:—"The *Field Naturalist* quotes the passage incorrectly, omitting 'when the flowers are neither visited by bees.'" In my chapter headed "The Sterilising Influence of Darwin's Net," where the quotation occurs, the bees in this reference—as they were excluded by the net—had nothing whatever to do with the subject, and so reference to them was omitted; the effect of the net and of the net alone on fertilisation was there being discussed.

Such are the passages which the reviewer cites as misquoted or interpolated. I should have esteemed it a deep dishonour if I had knowingly misquoted any statement of Darwin, or had interpolated any words in quotations from Darwin, and should not lightly have excused myself even had it been done carelessly or unwittingly. To avoid all such charges like those of the reviewer, I distinctly state in the preface:—"We have carefully given the references to all the passages quoted, or referred to, in the following pages." This was done that every reader might find without trouble, if he desired, the original passages and could compare the quotation with them.

At p. 409, the reviewer cites from "The Primrose and Darwinism":—"In calm weather the net would prevent the free access of the wind and would prevent it from shaking, and so from freely disturbing and distributing the pollen" (p. 8), and states "not a particle of evidence is given from his point of view." The evidence in this case is supplied by Darwin himself:—"In all cases the flowers were protected from the wind" (Cr. and S.F., p. 23); and again, as quoted in Prim. and Dar., "The wind does hardly anything in the way of conveying pollen from plant to plant when insects are excluded" (F. of Fl., p. 93).

The reviewer says, "When the author ventures on suggesting a function we are liable to come across such a theory, as the orifice in the carina of Lotus is to serve for the ventilation of the pollen stored within the carina." As I spent three and a half to four years of my life in the uninterrupted study of physiology and its sister sciences, there still remains a sufficient residuum of its flavour in the cask that I can venture to assert that if your reviewer will only consult a competent physiologist about a pistil surrounded with packed pollen in a closed carina, like Fig. 13, p. 132 (Sowerby's "English Botany," v. iii.), of the Lotus, he will tell the reviewer that such ventilation of a cone, if not absolutely necessary in every season, yet would be absolutely necessary in some seasons, and would be very conducive in all seasons to the healthy fertilisation and fructification of the pod.

Finally, the reviewer states, "the author makes the astonishing statement that Darwin's predecessors are to be commended for strictly subordinating theory to natural facts. They thus happily avoided the error into which Darwin, in this instance at least, most assuredly and most conspicuously fell." The reference here is to the dimorphism of the primrose and to Darwin's statement in reference to such a state—"One form of Primula must unite with the other form in order to produce full fertility" ("Form of Flowers," pp. 49, 56). And again, "heterostyled flowers stand in the reciprocal relation of different sexes to each other" ("Form of Flowers," pp. 2, 28, 245).

The late Professor J. S. Henslow was acquainted with the heterostylism of the primrose as stated (and quoted) by me in the preface to the book, but Darwin alone fell into the error that "the two forms stood in the reciprocal relation of different sexes to each other." I will leave to the judgment of botanists who are also acquainted with the long-tongued *Hymenoptera aculeata* and Lepidoptera to decide the question in the spring by observing the flowers from the middle of March to the end of April, whether the short-styled primrose, though fully productive, is cross-fertilised by insects.

In the same way we will leave to all observers or naturalists, by their observing the flowers in the month of May, the question whether the *Arum* is not, with possibly some very accidental exceptions, "a purely self-fertilised flower." We know of no English plant which gives plainer and more easily observable evidence to the fact of self-fertilisation. This is our decided opinion after having examined more than 500 specimens of opened spathes and found in them no evidence to the contrary.

After examining these cases the reviewer will not, I think, "find it hard to tell why this book was written." But lest he should still after that find a difficulty, I will tell him myself. It was, and is, to show that artificial experiments conducted under a close-meshed net was an unnatural and very defective method to discover the operations of Nature in flowers when exposed to the unlimited influence of sun, wind, dew and other atmospheric agencies; and to show that Nature must be interpreted under the atmospheric conditions which she herself provides, and not under those conditions minimised and in some cases almost absolutely intercepted.

AUTHOR OF "PRIMROSE AND DARWINISM."

September 2.

IN my review of "The Primrose and Darwinism," I thought it necessary to call attention to the inaccuracy of the author in the matter of quotation, but I had not the least intention of accusing him of anything more than carelessness. For instance, in the case of *Sarothamnus*, to which he refers in his letter, I was quite ready to believe that the omission of words within inverted commas was an oversight. But in his letter he tells us that they were omitted because "the bees in this reference—as they were excluded by the net—had nothing whatever to do with the subject." He stands self-convicted of knowingly altering what he quotes, but I readily believe that he is guilty of nothing worse than ignorance of the usage of literary work.

The Field Naturalist objects to my statement that there are "several copyist's mistakes" as well as "interpolated words" on p. 191 of his book. I therefore give the passage in his book to which I referred, followed by the corrections needed to make it agree with "Forms of Flowers," ed. ii. p. 323 [1]

But in *Oxalis sensitiva* "the long-styled cleistogamic flowers are produced by long-styled plants; the mid-styled as well as the short-styled cleistogamic flowers are produced respectively by the other two forms."

The mistakes are:—

For "the long-styled *read* the "long-styled.

For produced by long-styled *read* produced by the long-styled.

For the mid-styled *read* and mid-styled.

For the short-styled *read* short-styled.

Dele, produced respectively.

If the Field Naturalist really considers this a justifiable sample of the art of citation I shall be surprised.

With regard to *Salvia tenori*, the Field Naturalist complains that I describe (p. 409) the words, "when they touched the net and the wind blew" ("The Primrose," &c., p. 11) as an incorrect quotation. When I read the phrase in question I was so much surprised to find these words attributed to Mr. Darwin that I turned to his book, where I found, "which touched the net when the wind blew." I still think that the Field Naturalist is not justified in placing within inverted commas a passage which does not occur in the original; nor can I agree with him that the correct and incorrect versions convey "exactly the same sense." This was the only inaccuracy in regard to *Salvia tenori* to which I called attention in my review; but I now learn, from the parallel passages given in the Field Naturalist's letter, that he quotes incorrectly the words "two or three flowers on the summits of three of the spikes," changing them by a not unimportant omission to "two or three flowers on the summits of the spikes."

Lastly, the Field Naturalist complains of my saying that he has not a "particle of evidence" for his point of view in regard to the supposed injurious effect of the net in keeping the wind from the experimental plants. He goes on: "The evidence in this case is supplied by Darwin himself. 'In all cases the flowers were protected from the wind.'" What we want is not evidence of protection from wind, but evidence that such protection has any hurtful effect on the reproductive organs of the plants.

The rest of the Field Naturalist's remarks do not seem to me to call for reply. THE WRITER OF THE REVIEW.

A Method of Treating Parallels.

In your issue of July 3, just to hand, Dr. Richardson suggests a method of treating parallels which differs from the orthodox Euclidean method. Improvements of a kind similar to that suggested by him will go far towards rendering the teaching of geometry more effective than it is at present. I differ from him to a slight degree in this particular instance, in that I consider it preferable to take the more general case of equal inclination of parallels to any straight line which cuts them as expressing the clearest and most useful conception of parallelism. By constituting sameness of direction the criterion of parallels—direction being purely relative, this sameness is determined by

[1] The passage is the same in edit. i.

reference to *any* other direction—the other theorems, common perpendicularity, equality of alternate angles, &c., are easily deduced.

I was pleased to read Dr. Richardson's letter, as it showed that others were working in the same direction as myself. Part of my time is devoted to teaching mathematics at the School of Mines in this town. This technical institution is attended in the evening by students who during the day are serving their apprenticeship in mechanical workshops. Although geometry is a subject which readily appeals to them, I have learnt the futility of presenting it to them under the garb of Euclid. Even if they had the courage to face the schoolboy's drilling in Euclid, I could not conscientiously ask them to devote their energies to a labour so unremunerative. I, for one, hope that Prof. Perry's efforts to harmonise the teaching of geometry and other branches of mathematics with the needs of engineering students will bear fruit, and that before the lapse of any considerable time. W. R. JAMIESON.

Gawler, South Australia, August 27.

Symbol for Partial Differentiation.

DR. MUIR's symbols (p. 520) may be very suitable for manuscripts or the blackboard, but the expense of printing them would be prohibitive. No book in which such symbols were used to any extent could possibly pay. On the other hand, the symbol $(dE/dv)_p$ can always be introduced into a paragraph of letterpress without using a justification or a vinculum; and this very much lessens the expense of printing. A. B. BASSET.

Fledborough Hall, Holyport, Berks, September 26.

Bipedal Locomotion in Lizards.

I HAVE recently observed bipedal locomotion (p. 551) in the case of *Calotes versicolor* in similar circumstances to those noted by Mr. Ernest Green, and have reason to believe that it also occurs in the case of several other Agamoid lizards that I have watched in the Malay Peninsula, though their movements are too rapid to admit of certainty. *Liolepis bellii*, however, certainly uses all four legs when in rapid motion, holding its tail in the air.

A Possible Meteor Shower on October 4.

ON Saturday last, October 4, at 7.45 p.m., I noticed the following phenomenon:—The sky was clouded entirely, when, happening to look to the west-north-west, I saw a well-defined streak of light, starting on a level with some trees in a small wood and moving roughly horizontally towards the south for an angular distance of about 30°. This was followed at about 3-second intervals by another and another, until I counted 43 of them. After this the interval became greater, and about 8 o'clock the phenomenon ceased. It appeared to be like a meteor shower partially hidden by a thickness of cloud. Assuming this to be true, I am afraid the radiant point was hidden by the trees before mentioned. The elevation would be about 15°. Perhaps some of your readers more favourably situated may be able to throw further light on the matter.

G. PERCY BAILEY.

Stonyhurst College, Blackburn, October 6.

FALL OF A METEORIC STONE NEAR CRUMLIN (CO. ANTRIM) SEPTEMBER 13.

THE writer of this note visited the scene of the fall of this meteorite yesterday evening, September 20, and learned that it occurred at about 10.30 a.m. (local time) on the date in question. The body is almost 10 lb. in weight and of a more or less irregular outline, and of the usual meteoric appearance. It bears strong evidence of fusion, shines with a metallic lustre on one side and is apparently truncated, a fragment—say about a third—having fractured off in its descent through the atmosphere. There is also a well-marked line or two of fracture still visible. The evidence at present is that it fell quite perpendicularly, there being no trace of slope or inclination in the hole, about 13–15 inches deep, which it made on striking the soil. Mr. Walker, of Crosshill, on whose holding it fell, says it was quite hot at first, and felt warm for almost an hour afterwards. Of course, a good deal of interest and local curiosity is naturally aroused, the usual query being "Where did it come from?" Possibly the data given above may help to furnish an answer to this question, although hardly yet sufficient to enable an orbit or trajectory to be computed for this—the third meteorite which has fallen in the British Isles within recent years. The occurrence was accompanied by the usual rumblings or detonations, but the estimations of the duration are here, as is usual in other similar instances, untrustworthy.

Crumlin is almost due west from Belfast, distance about 10 miles, lat. 54° 36′ N., long. 6° 12′ W.

W. H. MILLIGAN.

26 Cooke Street, Belfast, September 21.

[The delay in the publication of Mr. Milligan's letter has resulted from our sending it to Mr. L. Fletcher, F.R.S., who has furnished the following interesting notes upon the meteorite.—Editor, NATURE.]

During the past fortnight it has been stated in various Irish and English newspapers that a meteoric stone had been seen to reach the earth near the village of Crumlin, a few miles distant from Belfast, on Saturday, September 13, when the meeting of the British Association in that city was in mid course.

Such reports of meteoritic falls are by no means infrequent and are almost always based on mere misapprehension of fact; indeed, it is very seldom that a stone believed to be a meteorite is found on critical examination to have any valid claim to a celestial origin. As lately as last week, for instance, a supposed meteorite was sent to the Natural History Museum from Shropshire for inspection, and yet was undoubtedly a product of our own earth.

As twenty-one years had passed away since the fall of a meteoric stone in the British Isles and thirty-seven years since the fall of a meteoric stone in Ireland, to a person in London it seemed more likely that the Crumlin fall was mythical than that a heavenly body should have fallen after so long an interval near to the very city where so many men of science were gathered together; and it seemed in any case to be a matter of certainty that before the news of the fall had reached London the stone must already have passed into the possession of a private, perhaps foreign, collector.

Last week, impressed by the circumstantial character of the reports (especially that sent by Mr. Milligan, of Belfast, for publication in NATURE), and desiring further information, I telegraphed from South Kensington to Mr. Andrew Walker, on whose farm the stone was said to have fallen; in reply he stated that the stone was still in his possession and that it had not been examined by anyone who had made a special study of meteorites. Though in doubt as to the advisability of so long a journey on the basis of such evidence as was at the moment available, I left at once for Crumlin, and was relieved on arrival to find that the journey had not been made in vain; the stone was undoubtedly a true meteorite. That a high degree of excitement had been aroused in the district by the reports of a meteoritic fall will be manifest from the circumstance that during the interview with Mr. Walker no fewer than four different sets of visitors, some in carriages, some on foot, called to see the stone and the place where it had struck the earth; each visitor was allowed to handle the specimen and feel its weight. It was being stated in the village, but Mr. Walker said it was an exaggeration, that as many as 300 people had been to the farm in the course of a single day. Although Mr. Walker had been told by some of his visitors that it would be unlucky for him to part with a gift sent to him direct from heaven, he perceived that the stone would be best preserved elsewhere

than in a farmhouse; a change of ownership was accordingly effected, and on the following day the stone was safely deposited on the premises of the Natural History Museum, South Kensington.

The particulars of the fall, as given orally to me by Mr. and Mrs. Walker, are as follows:—

At 10.30 a.m. on Saturday, September 13, which was a cloudy morning, W. John Adams, who is in the employment of Mr. Walker at Crosshill farm, was gathering apples from a tree on the edge of the cornfield and near the house; he was startled by a noise of such a character that he thought it was due to the bursting of the boiler at the mill, which is a mile to the south and is situated near to Crumlin railway-station. Another loud noise, like that of escaping steam, was followed by the sound as of an object striking the ground near by, and a cloud of dust immediately arose above the standing corn at a spot only twenty yards away from where he was at work. Adams ran through the corn towards the cloud of dust and found a hole in the soil; thereupon he hurried to the farmyard for a spade, and within a quarter of an hour of the fall had extracted a black, dense stone, which had penetrated the soil to a depth of $1\frac{1}{2}$ feet and had then been stopped by impact against a much larger terrestrial stone. The black stone was hot and, according to Mr. Walker, was still warm to the touch even an hour later. There was a sulphurous odour. Two other men were working at a haystack twenty yards further away from the hole made by the stone and also heard the sounds. Mr. Walker, who is seventy-two years of age, had himself just gone into the house, which is close by, and heard nothing of the explosion. Mrs. Walker told me that she was in the lane on the far side of the house and heard a sound comparable for character with that made by a swarm of bees, though much more intense, or with the rattling noise made by a reaping machine; she said that others who had heard it had likened the same sound to that of a reaping machine which had run away. It may be mentioned that the sound of a reaping machine is at present very familiar to the observers, for the harvest is in progress. Mr. Walker had heard that the detonation was remarked at Antrim, five miles to the north of Crosshill; at Legoniel, nine miles to the east; at Lisburn, eleven miles to the south-east; and also at Lurgan, thirteen miles south-south-west by south. Mrs. Walker said that some of the hearers had taken the sound to herald the arrival of the Day of Judgment. As yet there is no certain information as to the direction of the line of flight of the meteorite.

FIG. 1.—The Crumlin meteorite (reduced to one-third the natural size). View showing the smoother faces, the concavities, and the crack probably caused when the meteorite struck a still larger terrestrial stone buried in the soil.

FIG. 2.—The Crumlin meteorite (reduced to one-third the natural size). View showing the two dominant kinds of surface. The face on the right was probably produced by the breakage of the meteorite at an early part of the journey through the earth's atmosphere.

As for the stone itself, it weighs 9 lb. $5\frac{1}{2}$ oz.; it is $7\frac{1}{2}$ inches long, $6\frac{1}{2}$ inches wide and $3\frac{1}{2}$ inches thick. Its form is irregular and distinctly fragmental; there are nine or ten faces, each of them slightly concave or convex; the edges are rounded. Five of the faces are similar to each other in character, and, except for minute pittings and projecting points, are smooth; they show those large concavities which are common on meteoric stones, and have been likened in shape to "thumb-marks"; the remaining faces are different in aspect and have a low ridge-and-furrow development; they are doubtless due to fractures during the passage of the stone through the earth's atmosphere, possibly to the break-up at the moment of detonation. A crack going nearly half-way through the meteorite at a distance of an inch from an outer face was probably caused by impact on the larger stone met with in the soil.

The meteorite is virtually completely covered with the characteristic crust which is formed during the passage of such bodies through the air; the crust is in parts black, in parts brown perhaps owing to the influence of the soil. On the smoother faces already referred to the crust is thicker than, and different in aspect from, that on the remaining faces. From this it is inferred that the meteorite broke up in the earth's atmosphere at an early part of its course, when the speed was still so enormous that the heat produced by compression of the air in front of the quickly moving stone was sufficient to scorch the newly broken surface, for a fresh fracture of the stone is quite light in colour. In one part the crust is iridescent in purple, blue and pink colours. Here and there bright particles of a metallic alloy of iron and nickel interrupt the continuity of the dark crust. On one of the smaller surfaces of latest fracture there is visible a section of a large flat nodule of the bronze-coloured protosulphide of iron, troilite, which is a characteristic mineral constituent of meteorites and is not found as a native terrestrial product. Owing to the presence of particles of nickel-iron dispersed through the stony matter, the meteorite affects the magnetic needle, though not to a great extent.

A mould of the meteorite has been made from which models will be prepared; a detailed mineralogical and chemical examination of the material of the stone will be at once begun.

Crosshill is a mile to the north of Crumlin, a small village on the line of railway between Lisburn and Antrim; it is twelve miles west of Belfast and $3\frac{1}{2}$ miles east of Lough Neagh, a sheet of water thirteen miles long and seven miles wide; it is thus possible that the remaining fragments of the mass which entered the earth's atmosphere may have fallen into the water. The distance of separation of stones belonging to a single meteoritic fall has not yet been observed to exceed sixteen miles; it has on several occasions been found to reach ten miles.

The Crumlin meteorite is the largest stone which has been seen to fall from the sky to the British Isles for eighty-nine years, and is larger than any which has fallen in England itself since the year 1795.

L. FLETCHER.

OPENING ADDRESSES AT THE MEDICAL SCHOOLS.

THE first week of October has again brought round the opening of the medical schools, and with it a series of addresses by distinguished members of the profession, in which the first year's man is told something of the calling in which he has elected to earn his livelihood. These addresses are this year perhaps more varied and interesting than usual; at any rate, even the cursory reader cannot help but be struck with the quantity and the quality of the advice of which the future practitioner has been during the last few days the recipient.

At Owens College, Manchester, the introductory address was delivered by Sir Dyce Duckworth. In it some points of great importance both to teachers, students and the profession at large were considered. In the present state of medical education in London, especially with regard to the development of the medical faculty of the University of London, the remarks of the lecturer under the heading of the standard of general education for medical students cannot escape the observation of those interested in this subject. It is well known that a supposed grievance of the London medical student, which has certainly been well aired, is that although he spends as much money, time and intellect on his medical curriculum as his fellow student at the Scottish universities, he obtains merely a license to practise, whereas the Scottish student receives what is certainly of more value in the eyes of the public, viz. a degree in medicine. Into this question Sir Dyce Duckworth did not enter, but his view seems to be that licenses should not be made more difficult or university degrees easier; in other words, that the distinction between the two should remain, and that the degree should be regarded as an indication of distinctly higher attainments conferred upon those already holding diplomas. Those interested in the obtaining of an efficient medical staff for the public services are strongly recommended to take to heart the somewhat ominous words of this experienced teacher.

At University College, Sheffield, the opening address was given by Sir Henry Howse, the president of the College of Surgeons. After some remarks pregnant with interest and suggestion upon the scientific training, viz. the biological, chemical and physical training, of the medical student, the lecturer passed on to the part of the curriculum devoted to practical training. Under this latter head, Sir Henry Howse emphasised the most important fact that no disease must be regarded as a textbook entity, but that each as it occurred in each individual patient possessed individual characteristics, and that successful treatment could only be attained by observing and allowing for these characteristics. The great effect of apparently small causes was aptly illustrated by the lecturer by showing the difference between a little excess of alkali or acid in the preparation of the liquor ammoniæ acetatis of the pharmacopœia.

At the Yorkshire College, Leeds, the opening address was delivered by Mr. Mayo Robson, who took for his subject the advance of surgery during the last thirty years. At the end of the lecture, the author referred to the advances made in medicine and predicted that the progress in the next century would be chiefly medical.

At Guy's Hospital, the opening of the winter session was celebrated on October 1 by a distribution of prizes and medals to the students who were successful last session by the Lord Mayor of London. The Dean read the report of the medical and dental schools and referred to the position of Guy's as a medical school in the reconstituted University of London, expressing a hope that the altered regulations for the matriculation examination would enable a larger number of London students to obtain the doctor of medicine degree.

The London Hospital Medical College opened its 118th session with an old students' dinner on October 1. In a long speech, the chairman of the hospital referred to the great size and enormous work the hospital was doing both in relieving the sufferings of humanity and in the cause of medical education.

A most interesting address was delivered at the opening of the sixty-first session of the London School of Pharmacy, on October 1, by Prof. W. Palmer Wynne, F.R.S. The subject was the changes which have taken place on what may be called the scientific side of pharmacy during recent years, and especially those in which progress in chemistry has played a part. Prof. Wynne discussed the connection between chemical composition and physiological action, and emphasised the extreme difficulty of reducing the results obtained in this connection to anything approaching law, at the same time admitting the great progress which had been made in this direction.

F. W. T.

NOTES.

WE much regret to see the announcement of the sudden death of Dr. J. H. Gladstone, F.R.S., in his seventy-sixth year.

MR. J. ALLEN HOWE has been appointed curator and librarian of the Museum of Practical Geology in succession to Mr. F. W. Rudler, who, as mentioned in our last number, has retired.

THE zoological, botanical and geological collections of Dr. Sven Hedin have, it is stated, been presented by the explorer to the University of Stockholm.

THE death is announced, at the age of sixty-one, of Dr. Julius Ziegler, who for nearly thirty years was at the head of the meteorological department of the Frankfort Physikalische Verein.

THE next annual congress of the Royal Institute of Public Health is to take place in Liverpool in, probably, the third week of July next.

AT the Royal Microscopical Society on October 15, a demonstration on "Rock Changes in Nature's Laboratory" will be given by Prof. T. G. Bonney, F.R.S.

REPORTS of the following earthquakes have appeared in the *Times* during the past few days:—Advices from Guam state that 180 shocks of earthquake were felt in that island on September 25. The marine barracks and other buildings at Agana were destroyed.—Three violent earthquake shocks were felt at Tiflis at 2.30 a.m. on Saturday last, October 4.—A severe earthquake, lasting two minutes, was felt at New Marghilan, Ferghana, on Monday afternoon, October 6.

A telegram from the Governor of Martinique states that Mont Pelée is again emitting clouds and that rumblings are being heard. There has been an overflow of hot water from the crater in the region of Basse-Pointe, and slight earthquake shocks have been felt at Bourg Sainte Marie and at Bourg Trinité. A telegram from Kingstown, St. Vincent, reports that a slight eruption of the Soufrière occurred on the evening of October 1 after a week's tranquillity. The volcano was quiet on October 2.

At the opening ceremony of the new session of the Royal College of Science, held in the lecture theatre of the Victoria and Albert Museum on October 2, the Huxley gold medal was for the first time awarded to Mr. J. E. S. Moore, associate of the College, in recognition of work which he has already carried through and is still continuing in the Huxley Research Laboratory, in connection with his investigations into the African lake fauna and his studies in cytology and nuclear metamorphosis, commenced at the Naples Zoological Station. The medal is intended as an award for research carried out in the Huxley Laboratory in some branch of natural science in which Huxley was distinguished. The recipient has the option of a silver-gilt medal, and the award is in either case accompanied by the balance of the interest on the capital sum invested for the purchase of books, instruments or as an aid to research.

The Official Reports of the Belgian Antarctic Expedition have been presented by the Belgian Government to the Scottish Antarctic Expedition, which is shortly to take its departure. Mr. W. S. Bruce, the leader of the expedition, has also received a telegram from Lieut. G. Lecointe, of the recent Belgian expedition, wishing him success.

Captain Sverdrup and the other members of his recent expedition were entertained by the Geographical Society at Christiania last week. It was announced at the gathering that the Grand Cross of the Order of St. Olaf had been conferred upon Captain Sverdrup, that the Fram medal in gold was to be bestowed upon Peter Henriksen, and that the other members of the expedition were to receive the same in silver.

At a meeting of the local Society for the Prevention of Consumption held in Newcastle-upon-Tyne on Thursday last under the chairmanship of Mr. Watson Armstrong, it was decided to build a sanatorium for fifty patients at a cost of 50,000*l*., towards which the sum of 8000*l*. was subscribed at the meeting. Of this amount the chairman contributed 4000*l*.

Arrangements are already in progress for the next meeting of the Australasian Medical Congress, which is to be held at Adelaide in 1905 under the presidency of Prof. E. C. Stirling, F.R.S. The business is to be conducted in seven sections, as follows:—Medicine; surgery; gynæcology; diseases of eye, ear and throat; anatomy, physiology, pathology and pharmacology; public health; State medicine and medical ethics.

Dr. Logan Taylor set sail last week in charge of an expedition which has been sent by the Liverpool School of Tropical Medicine to inquire into the health conditions of the Gold Coast, reports having from time to time during the past year reached this country as to the ill-health which has been prevalent in the colony. The expedition will not be occupied so much with research work as with practical operations against the unhealthy conditions of the principal towns, and it will, so far as possible, work in conjunction with the medical staff of the colony.

In continuation of the announcement made a few weeks ago (September 4, p. 446), we learn from the *Times* that a resolution has been published stating that the Government of India has come to the conclusion that central authority is needed to ensure that the work of scientific research in India is distributed to the best advantage, that each investigator confines his researches to the subject with which he is most capable of dealing, and that energy is not wasted by the useless duplication of inquiries or misdirected by lack of cooperation amongst the various departments. Hence a board of scientific advice is to be formed, comprising the heads of the Meteorological, Geological, Botanical, Forest, Survey, Agricultural and Veterinary departments, and other scientific officers of special attainments. This board is to prepare every year a general programme of research and a report describing what has been done. The main object of the scheme is to promote the economic development of the country. The resolution mentions the various scientific officers appointed in recent years, and says that the development of machinery in the different departments has rendered more essential than ever the coordination of scientific inquiry. The special Indian correspondent of the *Lancet* points out that to complete the scheme of the Government another advisory board, similarly constituted to that already referred to, is required for the original investigation of human diseases. There are many complaints, he says, towards the understanding of which clinical observation has done little, and more scientific research upon them is wanted.

We learn from the *Isle of Man Times* that on Saturday last the Isle of Man Natural History and Antiquarian Society paid a visit to the new buildings at Port Erin utilised by the Insular Government and the Liverpool Marine Biology Committee for the purposes of a biological laboratory and museum, and also as a fish hatchery. An interesting address was given by Prof. Herdman, director of the biological station, who explained the purpose the laboratory was intended to serve in the way of education and scientific research, and referred to the advantage of bringing students into contact with the living animals as they were enabled to do in an institution of this character. He thought the principal work of the fish hatchery would be the breeding and rearing of lobsters and flat fish. Mr. P. M. C. Kermode, the hon. sec. of the Society, unveiled a bust of Edward Forbes, which he has presented to the new institution, and gave a brief address on the life and work of this illustrious biologist, who was born in the Isle of Man and accomplished considerable work in Manx natural history. Mr. Isaac Thompson also spoke in receiving the bust on behalf of the Liverpool Marine Biology Committee, and made an appeal for scientific publications for the station library; and Sir James Gell (the acting governor) alluded to the part which the Tynwald Court had taken in providing the new building and the support given to the project by Deemster Kneen. The proceedings terminated with an inspection of the tanks in the aquarium, the microscopic specimens in the gallery and the local type collection in the museum gallery, all arranged by Mr. H. C. Chadwick, the resident curator of the institution. In the afternoon the Society paid a visit to the Neolithic Stone Circle on the Meayll hill.

The New South Wales Government has recently made an experiment with the object of introducing European flat-fishes to the colony. At the time of arrival of the consignment of fishes, there were alive 560 plaice, twenty English soles, three Mediterranean soles and one female lobster. The experimen is reported to have quite come up to the expectations of the fisheries commissioners, as, although some of the fish dispatched died on the voyage out, they were looked upon only as of secondary importance in the experiment, all the special arrangements baving been made to suit the plaice.

It is stated in the *Scientific American* that Prof. R. Fessenden, whose system of wireless telegraphy is at present receiving the attention of the United States Government, has announced his intention of resigning his position in the

Weather Bureau, and that stations equipped with his instruments are shortly to be located along the Pacific coast, for use in the dissemination of the weather reports throughout that part of the country.

AT the festivities held in Bologna on the occasion of Mr. Marconi's return to his native town, Prof. Augusto Righi, in congratulating his former pupil on his successes, spoke to the following effect:—Perhaps no one can appreciate better than I his exceptional inventive power and his unusual intellectual gifts. I remember with great pleasure his visits when quite a young man, for asking my advice, for explaining his experiments, made with simple apparatus ingeniously put together, and for keeping me informed of his new projects, in which his passion for applied science always stood out. Even then I predicted that he would sooner or later attain fame. The system of wireless telegraphy which he derived from Hertz's classical experiments . . . is the most pleasing transference to the field of practical industry of those instruments and principles which might have seemed to be relegated to the domain of natural philosophy. Science always contains the germs of every unexpected marvel, and never has a seed fallen in ground that is more fertile or more suitable for causing it to germinate and transform into a fine and healthy plant. It is to the credit of Marconi that he has once more proved how much those are in error who regard with disdainful or indifferent eyes the work carried on continuously in the silence of the laboratory by the modest and disinterested scientific students, and who only appreciate science in proportion to the immediate uses that can be obtained from it. They do not know that even from the most abstruse result, a sympathetic mind may unexpectedly derive one of those applications which accelerate the advance of humanity on the path of progress and social welfare.

IT is suggested by Mr. R. Hedger Wallace in the October number of *Nature Notes* that Gilbert White's house, which, as has already been stated in these columns, is offered for sale, should be purchased and used as a school of nature-study. "What," says Mr. Wallace, "could well be housed at Selborne, and would assist the nature-study movement, is a library—say the 'Gilbert White Memorial Library'—which would illustrate what has been and is the influence of his teaching over the wide world—especially the English-speaking world. The number of such books is by no means small, and when once the library is formed, if it be kept up to date, it would be of very great service indeed to all interested in nature-lore and nature-studies."

AT the suggestion of the Astronomer Royal for the Cape, Mr. R. T. A. Innes, of the Royal Observatory, Cape of Good Hope, has made special observations in order to decide whether the stars marked ? in the Cape Photographic Durchmusterung really exist or not. Using a 7-inch refractor, Mr. Innes has found that all these stars except seventeen do exist.

THE application of the stereoscope to lantern projections has proved a fruitful field for the ingenuity of inventors. M. J. Macé de Lépinay now describes a very simple method of producing the desired effects. He projects two pictures side by side on the screen, and provides each observer with a pair of prisms the angle of which depends on the distance of that observer from the screen. Taking the two images at a distance of one metre apart, the angles of the prisms used are 12°, 10°, 8° and 6° for distances of 4·5, 5·4, 6·8 and 9 metres, the accommodatory power of the eye enabling intermediate distances to be used without further multiplication of prisms. One of the advantages of the system is the convenient and portable character of the prisms when mounted in the form of spectacles for observing the projections.

PROF. RINALDO FERRINI contributes to the Lombardy *Rendiconti* a short note on the calorimetric determination of high temperatures. A mass of platinum or nickel being heated to the temperature to be measured and then plunged into a water calorimeter, the rise of temperature determines the number of units of heat given out by the metal, and it is only necessary to know the specific heat of the metal at different temperatures in order to determine the initial temperature. Taking an approximate algebraic formula for the relation between specific heat and temperature, Prof. Ferrini deduces a linear equation for the temperature calculated with the use of nickel, and a quadratic equation for the temperature calculated by the use of platinum, within the limits considered in his investigation.

MESSRS. WITHERBY AND CO., the publishers of *Knowledge*, announce for early publication in book form the series of articles by Mr. E. W. Maunder entitled "Astronomy without a Telescope," which has been recently running through *Knowledge*.

WE are glad to notice that a new and cheaper edition of Prof. L. C. Miall's admirable book "Round the Year" has been issued by Messrs. Macmillan and Co., Ltd. In this popular form the book will doubtless be much in favour in schools where nature-study is encouraged.

THE secretary of the National Home Reading Union informs us that the new syllabus of subjects for the coming session—the fourteenth—of the Union is now ready for distribution. We notice that among the subjects included in the special courses are geology, Egyptian archæology, physiology and the laws of health. Information as to fees, text-books, &c., can be obtained from the secretary of the Union, Surrey House, Victoria Embankment, W.C.

THE October issue of *Climate*, the interesting and useful organ of the Livingstone College at Leyton, contains many items relating to health and travel which should be of service to travellers, *e.g.* among its contents are to be found illustrated interviews with Sir Harry Johnston, respecting "An African Equipment," and Dr. H. White, concerning "Life and Travel in Persia"; there are also, among other things, notes on "Kashmir from a Climatic Standpoint" and the progress of the various campaigns against malaria.

MR. J. C. NIMMO promises, "Fragments in Philosophy and Science," by Prof. J. Mark Baldwin; "History of the Babylonians and Assyrians," by Dr. H. Winckler; and new editions of Rev. F. O. Morris's "A History of British Birds," six volumes (illustrated), and "Natural History of British Moths," four volumes (illustrated).

IN Messrs. Hutchinson and Co.'s new list of announcements we notice:—"British Fresh-water Fishes," by Sir Herbert Maxwell, Bart., F.R.S.; "Fishes of our Seas," by F. G. Aflalo, W. Senior and F. B. Marston; "British Birds," by Aubyn Trevor-Battye; "British Butterflies and Moths," by F. Edward Hulme; and "British Mammals," by Sir Harry Johnston, G.C.M.G., K.C.B., all in the Woburn Library, and each illustrated; "The *Polar Star* in the Arctic Seas," by H.R.H. the Duke of the Abruzzi, in two volumes (illustrated); "Lord Lilford on Birds," a collection of unpublished writings by the late Lord Lilford, with contributed chapters on falconry and otter hunting, his favourite sports, edited by Aubyn Trevor-Battye, in parts (illustrated); "Our Poultry and all about Them," by Harrison Weir" (illustrated); "Hillside, Rock and Dale," bird life pictured with pen and camera by Oliver G. Pike; "Lizards, Living and Extinct," by T. Saville-Kent (illustrated); "The Insect Book of North America," by Dr. L. O. Howard (illustrated); "The Butterfly Book of North America," by W. J. Holland (illustrated).

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mrs. E. L. Francis; a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by the 4th Co. Army Service Corps; an Anubis Baboon (*Cynocephalus anubis*) from West Africa, presented by Mr. R. D. Whigham; a Formosan Deer (*Cervus taëvanus* ?) from China, presented by Captain Percy Scott, H.M.S. *Terrible*; three Herring Gulls (*Larus argentatus*), European, presented by Mr. F. W. Hunt; a Land Rail (*Crex pratensis*), British, presented by Miss Elsie E. Hutton; a Schmidt's Monkey (*Cercopithecus schmidti*) from East Africa, a Black-cheeked Monkey (*Cercopithecus melanogenys*) from West Africa, two Rhesus Monkeys (*Macacus rhesus*), an Indian Python (*Python molurus*) from India, a Brown Macaque (*Macacus arctoides*) from Burmah, an Amphiuma (*Amphiuma means*) from North America, a Lion Marmoset (*Midas rosalia*) from South-east Brazil, two Eyras (*Felis eyra*) from South America, deposited.

THE SCIENTIFIC AND TECHNICAL EXHIBITS AT THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THIS section of the Royal Photographic Society's exhibition appears to be rather smaller than on the two previous occasions, that is, since the larger accommodation of the New Gallery made it possible to represent adequately this side of photographic work. We hope that this is not an indication that the section is receiving less attention and is likely to suffer extinction, the fate that we regret to observe has overtaken the apparatus section, except, indeed, so far as concerns the trade stalls and a few exhibits that appear to be out of place in any of the existing departments.

The most striking novelty in the Gallery is a "parallax stereogram" shown by Mr. F. E. Ives. No details are furnished, but we believe that the photograph is taken by means of a lens of large diameter obscured except for two apertures, one on each side, so that it acts in a similar way to the two lenses of the ordinary stereoscope camera, but that the two images are superimposed. In front of the sensitive plate there is placed a screen with vertical lines on it, alternately opaque and transparent, at such a distance that each image will impinge upon the plate in narrow, vertical strips and in the shadows of the opaque lines cast by the light transmitted by the other opening in the lens. The two images are thus received on the plate in narrow, alternating strips. For viewing, the eyes take the place of the openings in the lens, the lined screen remaining in position to keep the two images separate. The correct position for the eyes is indicated by two holes in a board, no other apparatus being necessary. The effect is perfect.

The only example of colour photography by the Lippmann process is a photograph of the spectrum of the arc light by Mr. Edgar Senior. This is an improvement on Mr. Senior's previous noteworthy results, being taken with a narrower slit, but still the colours shown are not quite the same as those which one sees in the direct spectrum. It seems not unlikely that the differences are inherent in the process. Of other prints in colour, Mr. Brewerton contributes some in which the blue print is in Prussian blue, and the red and yellow superposed carbon prints, and Miss Acland some copies of miniatures by a modification of the Sanger Shepherd three-film process. These results are admirable, but they are not convincing. It would be better if an object were used less valuable than a precious miniature and more convenient than a landscape, so that the object and the copy could be exhibited side by side. It is well known that very good results can be obtained; we want now to see how near they are to perfection.

Mr. Hort Player exhibits some splendid examples of his method of copying engravings by superposition. The ordinary relative positions of the engraving and the sensitive paper are reversed, the light passing through the sensitive paper before it illuminates the engraving. A yellow screen is used, and potassium iodide is added to the developer. The whiteness of the ground, the blackness of the lines and the sharpness of the detail are excellent.

Photomicrography is well represented. The most notable examples are a series of photomicrographs taken in connection with the bacterial treatment of sewage, exhibited by Dr. Clowes. The enlargements vary from about natural size up to three thousand diameters. These fifty or more photographs may well be accepted as a model of what this kind of technical work should be. Mr. Ives has twelve photomicrographs made with a small and simple apparatus that is not described. The results would do credit to any apparatus, and show what may be done by care and skill without elaborate conveniences. Among the other work of this class that deserves commendation is a series of microphotographs of etched alloys by Mr. Earnest A. Lewis.

Astronomical and spectroscopic photography is well represented by very fine work from Sir Norman Lockyer, Captain Hills, the Greenwich Observatory and others. Some of the spectra have no wave-length scale attached, or any other indication of the part of the spectrum represented, and others bear no indication of the facts sought in their preparation or of the facts that the spectra demonstrate. If a little information of this kind were invited by the Society's officers and incorporated in the catalogue, the exhibits would gain vastly in interest. This want of information is also manifest in the "multiple lightning flash," fourfold, by Mr. J. Howden Wilkie, presumably taken with a swinging camera, and in other cases.

There are many other exhibits that deserve more than a passing mention. Snow formations, huge "caps" and "mushrooms" are illustrated by Mr. Vaughan Cornish (see p. 453 of this volume). Balloon photographs, Röntgen-ray work, the photography of animals and meteorological photography are represented by collections of good and in some cases unique examples.

THE BRITISH ASSOCIATION AT BELFAST.

SECTION K.

BOTANY.

OPENING ADDRESS BY PROF. J. REYNOLDS GREEN, M.A., SC.D., F.R.S., PRESIDENT OF THE SECTION.

THE visits of the British Association to a particular city recur with a certain irregular frequency and bring with them a temptation to the President of a Section to dwell in his opening Address on the progress made in the science associated with that Section during the interval between such consecutive visits. This course possesses a certain fascination of its own, for it enables us to realise how far the patient investigations of years have ultimately led to definite advances in knowledge and to appreciate the difficulties that have involved disappointments, and that still have to be surmounted. We like to look back upon the struggles, to record the triumphs, to deplore the failures and to brace ourselves for new efforts. The opportunity afforded hereby for criticism of methods, for reconsideration of what have been held to be fundamental principles, for the laying down of new lines of work based upon longer experience, shows us how desirable such a periodical retrospect may be.

Standing as we do almost at the threshold of a new century, it seems particularly advisable that we shall occupy our thoughts with some such considerations to-day. I do not wish, however, so much to dwell upon the past and to lead my hearers to rest in any way satisfied with the achievements of the last century, phenomenal as they have been, as to direct attention to the future and to place before you some of those problems which at the opening of the twentieth century we find awaiting investigation, if not solution.

I can only attempt to deal with a small portion of the botanical field. These are the days of specialisation, and when anyone is said to be a botanist, the question which arises at once is, Which particular section of botany is he associated with? The same principle of subdivision which cut up the old subject of Natural History into Zoology, Botany and Geology has now gone further as knowledge has increased, and three or perhaps four departments of botany must be recognised, each demanding as much study as the whole subject seemed to only fifty years ago. I shall therefore confine my remarks to-day to the field of vegetable physiology.

I should like at the outset to recommend this section of botanical work to those of the younger school of botanists who

are contemplating original research. To my mind the possibilities of the living organism as such present a fascination which is not afforded by the dry bones of morphology or histology; valuable as researches into the latter are, they seem to me to derive their importance very largely from the past, from the possibility of indicating or ascertaining the line of descent of living forms and the relation of the latter to their remote ancestors. The interest thus excited seems to me to be rather of an academic character when compared with the actual problems of present-day life, its struggles, triumphs and defeats in the conflict for existence waged to-day by every living organism. The importance of the study of physiology as bearing upon the problems of the morphologists has, I need hardly say, been fully recognised by the workers in that field. I may quote here a sentence or two from the Address of one of my distinguished predecessors, who said at Liverpool, "There is a close relation between these two branches of biology, at any rate to those who maintain the Darwinian position, for from that point of view we see that all the characters which the morphologist has to compare are, or have been, adaptive. Hence it is impossible for the morphologist to ignore the functions of those organs of which he is studying the homologies. To those who accept the origin of species by variation and natural selection there are no such things as morphological characters pure and simple. There are not two distinct categories of characters—a morphological and a physiological category—for all characters alike are physiological."

But apart from the considerations of the claims of vegetable physiology based upon its own intrinsic scientific value and the interest which its problems possess for the worker himself, and upon the place accorded to it as its relationship to morphology, it must, I think, be recognised as being of fundamental economic importance, especially in these times of agricultural depression. For many years now it has been recognised that agriculture is based upon science; that it involves indeed properly the application of scientific principles to the cultivation of the soil. But when we look back upon what has passed for agricultural science since the alliance between the two has been admitted, we cannot but recognise how lamentably deficient in breadth it has been. The chemical composition of the soil and subsoil has been investigated with some thoroughness in many districts of the country. The effect of its various constituents on the weight and quality of the crops cultivated in it has been exhaustively inquired into, and a considerable amount of information as to what minerals are advantageously applied to the soil in which particular plants are to be sown has been acquired. A kind of empirical knowledge is thus in our possession, in some respects a very detailed one, quantitative as well as qualitative records being available to the inquirer. But elaborate as have been the researches in these directions, and costly and troublesome as the investigations have been, they have been hardly, if at all, more than empirical. Till quite recently the physiological idiosyncrasies of the plants round which all these inquiries centred were almost entirely ignored. No serious attempt was made to ascertain the way in which a plant benefited by or suffered from the presence of a particular constituent of the soil. What influence, for instance, has potassium or any of its compounds upon the general metabolism of the plant? Does it affect all its normal nutritive processes, or does it specially associate itself with some particular one? If so which one, and how does the plant respond to its presence or absence by modifying its behaviour? So with phosphorus again; hardly any investigation can be made into the nutritive processes of a plant without this element becoming more or less prominent. In some cases the empirical results already referred to show an enormous influence on the crop exerted by soluble phosphates in the soil or the manure applied to it. But what can yet be said as to the *rôle* played by phosphorus or by phosphates in the metabolic processes in the plant? Further, how do different plants show different peculiarities in their reactions to these various constituents of the soil? For the advance of agriculture the study of the plant itself must now be added to the study of the soil. The fact that it is a living organism possessing a certain variable and delicate constitution, responding in particular ways to differences of environment, capable of adapting itself to a certain extent to its conditions of life, dealing in particular ways with different nutritive substances, must not only be recognised, but must be the basis for the researches of the future, which will thus supplement and enlarge the conclusions derived from those of the past, in some respects correcting them, in others establishing them on a firmer basis.

In pressing upon the younger school of botanists the importance of this line of research, I do not wish to minimise the difficulties that accompany it. Difficulties of method assume considerable magnitude, for we have here no question of section cutting and microscopic examination. Vegetable physiology is allied very closely to other sciences, and research into its mysteries involves more than a preliminary acquaintance with them. Especially must one point out the importance, indeed the necessity, of acquaintance with a certain range of organic chemistry and with chemical methods of work. In certain directions, too, physics are as much involved as chemistry in others. The bearing of these sciences in particular directions will be referred to later.

I fear another obstacle stands at the threshold of research which looks sufficiently formidable. The so-called fundamental facts of vegetable physiology have been laid down with sufficient dogmatism in text-books by many writers whose names carry with them such weight that it appears almost heresy to question their statements. We have been content to accept many things on the authority of the great workers of the past, with the result that the advance of knowledge has been hindered by such acceptance of what were deemed facts, but were really inaccuracies. We may refer, for instance, to the statement made by Boussingault, and accepted by most botanists ever since his time, that the absorption of carbon dioxide from the air takes place by means of solution in the cuticle of the epidermal cells of plants and thence passes by diffusion to the seats of photosynthesis. Only comparatively recently has this been shown to be erroneous. If, however, it is once recognised that authority is fallible, this apparent obstacle becomes the opposite. The more evident questions have not yet been solved, leaving only the more difficult ones for the present-day worker.

Recognising the importance of work in this field, and realising that with the advent of a new century new departures must be taken, I have thought I might venture to direct the thoughts of my hearers, many of whom I may call my colleagues, to the present position of certain problems which have long been the subjects of speculation and which offer the prospect, if not of complete solution, at any rate of considerable advance if investigated by modern methods.

I turn first to a few questions connected with the nutritive problems of plants in general

There are several theories abroad as to the progress of events during photosynthesis, none of which can be regarded as entirely satisfactory. For many reasons it seems desirable that this question shall be thoroughly investigated in the light of the present condition of both chemical and physical science. I may perhaps venture to recall to you the principal hypotheses of carbohydrate formation which have been advanced, so that its present position may be properly appreciated.

The view that has met with the widest acceptance is that of Baeyer. On his hypothesis the carbon dioxide absorbed is decomposed under normal conditions to yield carbon monoxide and oxygen; a corresponding and coincident decomposition of water leads to the production of free hydrogen and oxygen. The oxygen from both sources is exhaled, while the carbon monoxide and hydrogen combine to form formaldehyde. The formaldehyde gives rise by a process of polymerisation to some form of sugar.

A modification of this hypothesis has been advanced, which suggests that the preliminary decomposition of the carbon dioxide and the water may not take place, but that by a rather less violent reaction between them the formaldehyde may be formed and the oxygen liberated.

Erlenmeyer has suggested a somewhat different course of reaction, yielding substantially the same results. He thinks it possible that the first interaction of carbon dioxide and water leads to the formation of formic acid and hydrogen peroxide, and that these subsequently interact with each other, yielding formaldehyde and water and giving off oxygen.

Many years after the views of Baeyer appeared, a hypothesis of a different nature was proposed by Crato. He suggests that the carbon dioxide after absorption becomes ortho-carbonic acid, and that this remains in solution in the cell sap. This acid has the structure of a closed benzene ring in which six molecules are linked together. This becomes decomposed, liberating six molecules of water and six molecules of oxygen,

and forming a hexavalent phenol which subsequently undergoes a molecular rearrangement and becomes glucose.

Yet another suggestion was made by Bach in 1893. He points out that when sulphurous acid is exposed to light it becomes transformed to sulphuric acid, sulphur and water being split off, and he argues that a process analogous with this may take place in a leaf. The carbon dioxide uniting with water would form carbonic acid, and this might then split up in the same way as the sulphurous acid. The carbon and the water thus split off are on this hypothesis not set free separately, but in combination as formaldehyde. The higher carbon acid, to which Bach ascribes the formula H_2CO_4, splits up into carbon dioxide and hydrogen peroxide, and the latter is decomposed into water and free oxygen.

Lieben has still more recently put forward the view that formic acid and not formaldehyde is formed by the first decompositions. He has found that leaves of grasses and various trees yield formic acid among other products when mixed with their own weight of water containing a trace of sulphuric acid and distilled with steam. Moreover, when carbon dioxide is acted upon by nascent hydrogen the only product is formic acid.

These speculations afford many points which might be well made the starting places of research. The views of Baeyer have met with most acceptance, though but little success has attended the few efforts that have been made to establish them by experiment.

They involve several definite stages of action, of which the most important seem the production of carbon monoxide and hydrogen, the formation of formaldehyde and the construction of a sugar. The last two questions arise also in connection with the hypothesis of Bach

If we examine the work that has been published bearing on the probability of the formation of carbon monoxide in the plant we find little that is satisfactory. The statements that have been made are opposed to the idea that carbon monoxide is of value in nutrition ; it is said that when supplied to a plant instead of carbon dioxide it does not lead to the formation of carbohydrates. It is further advanced that this gas is of a very deleterious nature, and if formed would result in the speedy death of the protoplasm of the cell in which it originates. This idea is, of course, specious ; but it does not appear to be well founded. The deadly character of carbon monoxide when inhaled by a human being depends upon a peculiar interference which it causes with the oxygen-carrying power of the red blood corpuscles. The pigment hæmoglobin to which these little bodies owe their usefulness forms a loose chemical combination with oxygen, the compound being formed in the blood vessels of the lungs and being decomposed with the liberation of the oxygen in those of the tissues of the body. It is evident, therefore, that the value of the corpuscles as oxygen-carriers depends upon their hæmoglobin. When this pigment is exposed to carbon monoxide it combines with it in the same way as it does with oxygen, forming, however, a more stable compound. The affinity for this gas which the pigment manifests is very considerable. Hence the poisonous nature of carbon monoxide. It is easily seen that the latter is a poison because it throws out of gear and temporarily paralyses a most essential part of the mechanism of respiration, effectually preventing oxygen from reaching the tissues of the body. There is no evidence here that it exerts even a deleterious influence upon the living substance itself. The only poisonous effect it would be able to exert on the plant would necessarily be of the latter character, for there is no oxygen-carrying mechanism that could be interfered with. We cannot lay any stress, therefore, on the objection to Baeyer's view, based upon the action of carbon monoxide upon the human organism.

Another possibility may, however, be mentioned. As we shall see later, there are certain resemblances between hæmoglobin and chlorophyll, the vegetable pigment concerned in photosynthesis. May not carbon monoxide enter into some relationship with the latter, and thereby indirectly hinder its activity ? Of that, however, there is no trustworthy evidence, the facts known to us rather pointing in the opposite direction.

The idea of the poisonous nature of this gas may easily be subjected to experimental examination. It would appear easy to expose a plant to an artificial atmosphere made up to different partial pressures of carbon monoxide, to expose it in such atmospheres to various conditions of warmth and illumination and to note the effect produced. It would seem possible to examine a great variety of plants in that way, to try both aërial and aquatic forms, and indeed to test the matter exhaustively. It must be borne in mind, however, that the solubility of carbon monoxide in water is extremely small, and that there may be a great difficulty in getting it brought within the scope of the influence of the living substance on that account. It must necessarily be in solution in the cell sap before it can affect the activity of the chloroplast. Even the relations of solubility are not, however, outside the range of experiment, and it may be that the slightly acid cell sap has not the same peculiarities as water as a solvent for the gas.

It is important, again, to take into account in such work the factor of sunlight, on which the power of photosynthesis depends. Should carbon monoxide prove capable of serving as a basis for the formation of carbohydrates, the question would arise, Is the activity of the chlorophyll in sunlight confined to the preliminary formation of carbon monoxide from the dioxide, or is the energy derived from the light brought to bear upon the subsequent constructive processes ? We have little or no accurate information as to the way in which the energy is utilised after absorption by the chlorophyll.

This opens up a very important but very difficult line of work, which brings home to us the intimate dependence of vegetable physiology upon physics. The absorption of energy from without, in the form of the radiant energy of the solar rays, is certainly a fact, and to a certain extent we can picture to ourselves the way in which it is secured. The spectrum of chlorophyll shows us a number of absorption bands whose position corresponds with the position in the spectrum of the places where oxygen is liberated in photosynthesis. But the transformation and applications of energy in the body of the vegetable organism need much closer examination. The intimate relationship between the different manifestations or forms of energy and the ways in which they can be transformed into one another have been very minutely scrutinised in recent times. What then should hinder us from learning something much more definite than we at present know about these transformations in the *rôle* of vegetable life ? The electrical phenomena connected with the movements of the leaves of the Venus's fly-trap (*Dionaea muscipula*) have been examined with considerable completeness by Burdon Sanderson, and we have learned that the vegetable and animal organisms show considerable similarities in this respect. Recently, again, Bose has made important contributions to the subject of the electrical responses to stimulation that can be observed under particular conditions. A promising beginning has thus been made, but only a beginning. The electrical condition of the normal plant under different conditions of rest and activity has still to be investigated. If we return to the subject of photosynthesis and the work done by the chloroplast, may we not hope to discover something about the transformation and utilisation of the radiant energy associated somehow with this structure ? Considering the relations between the manifestations of energy which we appreciate respectively as light and electricity, it does not seem wildly improbable to imagine that the energy absorbed as the former may lead to a possible electrolysis of carbonic acid under the influence of the chloroplast, with the formation of carbon monoxide and oxygen. Pfeffer has suggested that perhaps the decomposition of the gas is not due to the light rays at all, and that they may exercise only a stimulating influence upon the chloroplast, the energy concerned being derived from heat rays directly absorbed, or heat vibrations derived from the more rapidly vibrating light rays. In this case is the decomposition brought about directly by the heat vibrations, or have we a transmutation into some other form of energy ? The whole subject seems at all events a promising subject for inquiry.

Another problem connected with the action of chlorophyll is associated with the absorption of radiant energy by the different regions of the spectrum. Bands of considerable intensity are noticeable in the blue and violet, though the deepest absorption takes place in the red. Yet Engelmann's classic bacterium method shows us that very little evolution of oxygen takes place in the position of these bands in the blue and violet. The fact that absorption of radiant energy and photosynthetic activity show no quantitative relationship is of course not new, but the reason remains still to be discovered. Van Tieghem has suggested an explanation which recalls to us the hypothesis advanced by Pfeffer, just alluded to. This explanation is that there are two factors concerned in the action of chlorophyll, the elective absorption of light, shown by the occurrence of the

absorption bands in the spectrum, and the calorific energy of the absorbed radiations. The failure of the rays of the blue and violet to effect photosynthesis, in spite of their absorption, would on this view be attributable to their possessing but little calorific energy. The latter is associated much more strongly with the deep band in the red, which is the seat of the maximum evolution of oxygen when the spectrum is thrown upon a collection of active chloroplasts. The heating rays alone are ineffectual, as shown by the fact that there is no liberation of oxygen in the region of the infra-red, due no doubt to the fact that chlorophyll does not absorb these rays.

Timiriazeff, in his classical researches on the liberation of oxygen by the leaves of the bamboo when exposed in tubes of small calibre to a large spectrum, found that the amount of carbon dioxide decomposed by leaves is proportional to the distribution of effective calorific energy in the spectrum.

Van Tieghem's hypothesis that this is a matter of calorific energy may prove to be erroneous, and yet his views may rest on some sound basis. It may be a matter in which electrical rather than calorific energy may be concerned.

Returning now to the chemical steps demanded by Baeyer's hypothesis, there are certain considerations which may be urged in favour of the view that carbon monoxide really occurs in photosynthesis. It has been ascertained by Norman Collie that when a mixture of gases containing a large proportion of carbon dioxide is exposed at low pressures in a vacuum tube to the action of an electric discharge from an induction coil, there is a very large formation of the monoxide, together with oxygen, in some cases as much as 70 per cent. of the gas undergoing decomposition.

Appealing to the experience of various observers, there seems on the whole to be a balance of evidence in favour of the power of plants to live and prosper in an atmosphere containing a very considerable percentage of carbon monoxide.

The question of the possibility of the latter replacing the dioxide, as the theory appears to require, is complicated very seriously by the differences of solubility between them. Carbon dioxide dissolves very readily in water and in cell sap; carbon monoxide is almost insoluble in either. As the amount of a gas taken up by a solvent depends, not only on its solubility, but upon its partial pressure, it is very evident that we cannot compare the two gases by admitting the same quantity of both to plants under simultaneous comparison. It is only necessary to supply the dioxide in the proportion of four parts in 10,000; but the almost insoluble nature of the monoxide makes it inevitable that from 2 to 5 per cent. shall be experimented with. The same question of solubility makes it almost out of the question to experiment with an aquatic plant.

It would be of considerable interest from this point of view also to inquire whether if carbon monoxide is liberated at the outset of the photosynthetic processes its combination with other groupings can take place apart from the action of chlorophyll. If so, the fungi should be capable of carbohydrate construction if supplied under proper conditions with the monoxide and with hydrogen. The proper conditions, however, might be extremely difficult to establish.

The next stage in the constructive process affords still ample room for investigation. The presence of formaldehyde is not the hypothesis of Baeyer alone, but is demanded according to Bach's views, though the stages of its hypothetical construction are not the same. We have therefore to ask whether formaldehyde can be detected in plants, and if so whether the conditions under which it may exist admit of its being considered an up-grade product in photosynthesis. Objections to the theory of its formation may be advanced, based upon its undoubtedly poisonous nature. Of all the antiseptics now available to the bacteriologists it is perhaps the most potent, even traces being fatal to the form of vegetable protoplasm which is found in bacteria. We may argue that it must be equally deleterious in the cell containing chlorophyll and to the chloroplast itself, as we have no reason to suppose that any difference in vitality exists between the protoplasm of different plants. At first sight this appears an almost insuperable difficulty in the way of the theory. Formaldehyde has, however, the properties of aldehydes in general, one of which is the power of condensation or polymerisation. It passes with extreme readiness into a much more inert form, para-formaldehyde, a body in which three molecules of the formaldehyde are grouped together. It is therefore possible that it may be prevented from exercising its deleterious properties by a transformation at once into this comparatively harmless modification. This will slowly decompose under proper conditions, giving off the free aldehyde.

Pollacci has stated that it is possible to extract formaldehyde from leaves. In his experiments he took such as had been exposed to light for a very considerable period and then macerated them in water. After a sufficient extraction he distilled the leaves, together with the water in which they had been steeped. The first portions of the distillate yielded reactions indicative of the presence of formaldehyde. His experiments do not enable us to say that free formaldehyde was there, for the more stable *para*-form would be likely to decompose during the distillation, so that the reactions would be explained without demanding the presence of the free aldehyde in the leaves.

But little success has attended hitherto the attempt to show that formaldehyde, in the presence of chlorophyll, or preferably, we may say, of chloroplasts, can give rise to carbohydrates. We have nothing more satisfactory than Bokorny's experiments, in which, after failing to set up photosynthesis in a filament of Spirogyra fed with formaldehyde, he succeeded when he supplied the alga with its compound with sodium-hydrogen-sulphite. Experiments on a more comprehensive scale, conducted on a variety of plants of different habits, are needed before we can regard the process as satisfactorily established.

We have further to pursue the problem by an inquiry as to the nature of the sugar first formed. Certain considerations lead to the view that it is probable that a sugar of the aldose type must be accompanied in the plant by a ketose. The hypothesis as stated by Baeyer, and so far accepted until quite recently, took no account of the latter. The aldose *grape sugar* was the one always suggested, and from this all others met with have been held to be constructed. The first appearance of a ketose, *lævulose*, or *fruit sugar*, has been associated with the hydrolytic decomposition of *cane sugar*, itself constructed presumably from the grape sugar. I fear sufficient attention has not been paid to probability or to the normal course of chemical action in framing our hypotheses, for it is rather difficult to see how some of the transformations somewhat dogmatically affirmed can possibly take place. I may refer in passing to the statement that in the digestion of fat or oil during germination part of it is converted into starch or sugar.

But to return to the construction of sugar. The condensation of formaldehyde, which can be brought about by the action of basic lead carbonate, leads to the formation of several sugars, each yielding its characteristic osazone. How far the condensation in the plant follows this is still uncertain. It is quite possible that stages intervene between formaldehyde and sugar of any kind. It has been suggested that formaldehyde in the presence of water may under the conditions obtaining in the leaf give rise to glycolaldehyde, a body which forms sugar very readily indeed. The formation of sugar directly from formaldehyde is a much longer process and is attended with greater difficulty.

I may call your attention here to the views of Brown and Morris traversing the theory of the primary carbohydrate being grape sugar. In their classical paper on the chemistry and physiology of foliage leaves, they have adduced strong evidence, based upon analyses of the sugar-content of leaves of *Tropaeolum majus*, that in this plant at any rate the first sugar to be formed is cane sugar. Whether or no this is the case in plants generally cannot at present be said, though it appears from many considerations probable.

The part played by chlorophyll in photosynthesis has already been touched upon. Remarkably little is known about chlorophyll itself. It has so far been found impossible to extract it from the chloroplast without causing its decomposition, and hence our ideas of its constitution, such as they are, are based upon the examination of something differing in some not well-ascertained particulars from the pigment itself. A remarkable relationship is known to exist between the latter and iron, for unless this metal is supplied to a plant its chloroplasts do not become green. But the condition of the iron in the plant is uncertain; it seems probable that it does not enter into the molecule of the pigment at all. A remarkable series of resemblances between derivatives of chlorophyll and derivatives of hæmatin, the colouring matter of hæmoglobin, has been brought to light by the researches of Schunck and Marchlewski, which is very suggestive. The same leaning towards iron is found in the two pigments, but in the case of hæmatin our knowledge is further advanced than in that of chlorophyll. The iron is known to be part of its molecule. It can by appropriate treatment be

removed, and a body known as *haematoporphyrin* is then formed, which presents a most striking similarity to a derivative of chlorophyll which has been named *phylloporphyrin*. The two pigments are almost identical in their percentage composition, the hæmatoporphyrin containing a little more oxygen than the other. Both seem to be derivatives of pyrrol. The most striking similarity between them is their absorption spectra, their ethereal solutions both showing nine bands of identical width and depth, those of hæmatoporphyrin being a little more towards the red end of the spectrum. Their solutions in alcohol and ether show the same colour and the same fluorescence. Though they differ in certain other respects, notably the facility with which they form crystals, it is impossible to deny that a close relationship seems probable. If this is established, we may by analogy perhaps learn something about the part played by iron in the action of the chloroplast, which so far has proved as obscure as the relation of the metal to the pigment. It is very suggestive to recall the resemblances between the two pigments, the one playing so prominent a part in animal, the other in vegetable life. Both are associated with a stroma of proteid, or possibly protoplasmic, nature, in which a solution of the pigment is retained, apparently after the fashion of a sponge. Both are concerned in metabolic processes in which gaseous interchanges play a prominent part. Both are in some way dependent on the presence of iron for their individuality, even if iron is not actually present in the molecule of both. The iron being removed, the derivatives which are found are almost identical. Further researches may throw a light on this curious relationship, perhaps showing that chlorophyll may enter into a combination with carbon dioxide as hæmatin does with oxygen. Such a combination might well be the precursor of the decomposition of the carbon dioxide which has been already spoken of.

We meet with another pigment in many plants the physiological significance of which has in recent years begun to attract some attention. This is the red colouring matter, *anthocyan*, apparently related to the tannins, which is developed especially in the young leaves of shade-loving plants when they become exposed to illumination exceeding the intensity which they normally encounter. The formation of this pigment is greatest in tropical plants, where it is found usually in the epidermis of the young leaves, though in some cases it extends to the mesophyll as well. The pigment seems in some way to be supplementary to chlorophyll, for its absorption spectrum shows that it allows all the rays useful in photosynthesis to pass through it. It is unlikely that it takes any share in photosynthesis. Several theories have been advanced to explain its presence; it may be simply to protect the delicate cells from the destructive action of too intense light, or to avert the evil of overheating from the solar rays. It has been suggested that certain rays hinder the translocation of starch, and that the pigment shields the cells from the incidence of such rays. Again, the view has been advanced that the red colour is important in accelerating the development of diastase from its antecedent zymogen, which has been found to take place under the influence of the rays of a certain region of the spectrum. While all these views have been advanced, however, there is little positive information bearing upon either the formation or the function of the pigment.

Very little progress has been made with the problem of the construction of proteid matter in the plant, which still confronts us. The question of its relation to the mechanism of photosynthesis has received some attention without leading to any satisfactory conclusion. Winogradski's success in cultivating the nitrate bacteria upon purely inorganic matter reveals an unexpected constructive power in some forms of vegetable protoplasm. The question of the energy made use of in proteid construction is in an equally unsatisfactory condition. Laurent, Marchal and Carpiaux have stated that the rays of the violet and ultra-violet region of the spectrum are absorbed and devoted principally to the construction of nitrogen compounds from the nitrates, or the compounds of ammonia, which are absorbed by the plant, while the intervention of the chlorophyll apparatus is unnecessary for this purpose. The experiments which they give in considerable detail upon this absorption carry much weight and appear conclusive. Unfortunately, other observers have failed to confirm them, so that at present the matter must be left open.

Among the problems connected with the nutrition of the plant, the part played by alcohol has recently come into prominence. Alcohol was originally associated only with the lower fungi, and especially with the yeast plant. Biological problems of grave importance arose in connection with the Saccharomyces, apart from what seemed at first the larger question, viz. the nature of fermentation. A prolonged study of the latter phenomenon led Pasteur to the view that alcoholic fermentation is only the expression of the partial asphyxiation of the yeast, and its efforts to obtain oxygen by the decomposition of the sugar. It is hardly necessary here to remind you of the controversies that centred about the question of fermentatinn and the theories held and abandoned as to its cause. The biological phenomena have, however, a claim now upon our attentinn in the light of some very remarkable researches that are calling for our attention and criticism to-day. Pasteur's explanation of the behaviour of the yeast was, as we have seen, such as to connect it with the respiration of the plant. When oxygen was withheld from active yeast, 60-80 parts of sugar disappeared for one part of yeast formed. When oxygen was present, not more than ten parts of sugar were decomposed for the same amount of yeast production. Undoubtedly the stimulus of asphyxiation materially stimulated the yeast metabolism.

But certain observations did not agree with Pasteur's explanation. An energetic fermentation takes place in the presence of oxygen, the plant multiplies extremely quickly, and its metabolism appears very active. Schützenberger argued against Pasteur's explanation with some force, emphasising these points of disagreement between his hypothesis and the facts, and claimed that the matter rather concerned nutrition than respiration. He based his view on experiments carried out to ascertain how respiration was affected under changed conditions.

The results he obtained were briefly the following:—

(1) In a watery liquid without sugar, but containing oxygen in solution, the quantity of oxygen absorbed in unit time by a gramme of yeast is constant, whatever proportion of oxygen is present.

(2) In a saccharine liquid containing albuminous matter as well as sugar, and with oxygen in solution, the same result is obtained, except that the quantity absorbed in unit time is greater.

(3) In two digestions carried on side by side for some time, one being supplied continuously with oxygen and the other deprived of it, the former produced most alcohol.

If the decomposition of the sugar had been the result of the respiratory activity of the yeast cells at the expense of the combined oxygen of the sugar, it would seem that fermentation should either not have taken place at all in the presence of free oxygen or that it should have been much less than in the other case, whereas the reverse is what is found. Hence Schützenberger advocated the view that the sugar is alimentary and not respiratory.

Certain facts more recently discovered support strongly the view that the nutrition of the yeast is the chief object of the process normally, though we cannot deny that when partial asphyxiation sets in, fermentation is resorted to by the plant in its difficulty, that it may obtain the energy normally supplied by the respiratory processes. The mode of decomposition of the sugar, however, the formation of alcohol and carbon dioxide, raises a question as to the exact form in which the nutritive material is supplied to the protoplasm.

Of these more recent discoveries, the work of Devaux on the trunks of trees may be mentioned first, as it seems to point to a similar problem to the one connected with yeast. Devaux examined the composition of the air in the interior of woody stems growing under normal conditions, and found that the proportion of oxygen it contains often sinks as low as 10 per cent., while in a few cases, in the most internal part of the tree, he found this gas to be entirely absent. The disappearance of oxygen becomes easier with every increase of temperature. The partial asphyxiation is attended by the formation of alcohol in the struggling tissue, the spirit being detected by cutting up the branches of the trees and distilling them with a large excess of water. Devaux's experiments were made upon a considerable variety of trees, among which may be noted *Castanea vulgaris*, *Pyrus domestica*, *Alnus glutinosa*, *Ulmus campestris*, *Sambucus nigra* and *Ficus Carica*.

Similar results have been obtained by Mazé in some researches on seeds. When a number of these are submerged in water, micro-organisms being properly guarded against, they do not readily germinate, but their weight nevertheless somewhat rapidly diminishes. In some of Mazé's experiments with peas, he

ascertained that this diminution was attended by a considerable formation of alcohol. Three parcels of forty peas were examined, weighing respectively 10, 17 and 27 grammes, and the experiments lasted six, twelve and twenty-seven days. He found the proportion of alcohol to the original weight of the peas was 2·34, 4·63 and 6·56 per cent. As the peas were submerged, and so kept out of contact with air, it seems possible to suppose we have here again an effect of asphyxiation. Other experiments, however, make this view unsatisfactory. He germinated twenty peas at 22° C. for seven days under normal conditions, till their axes were about 1½ inches long. He then covered them with water, in some cases leaving the terminal bud exposed to air. The development of the submerged plants stopped at once, and at the end of five days the liquid contained 130 milligrammes of alcohol. The seedlings whose terminal buds were exposed to the air continued to grow without showing any disturbance. Mazé concludes that the alcohol produced was utilised by them in their growth, and suggests that it is a normal and necessary product of the digestion of carbohydrate material in seeds in course of development.

He goes on to show that alcohol can be demonstrated to be present in plantlets that have germinated for forty-eight hours at 23° C. under normal conditions.

Another worker of great eminence who has found similar conditions to exist in normal vegetation is Berthelot. He put blades of wheat and leaves of the hazel in flasks, displaced the air by hydrogen, and distilled. In the case of the wheat he heated the flask to 94° C., in that of hazel he conducted the distillation by passing steam through the flask. In both he found the distillate contained alcohol. The quantity was not large, but still measurable; from 10 kilos. of leaves he obtained 10 grammes of alcohol.

Mazé claims to have found alcohol under normal conditions in the stems and leaves of the vine.

Mazé finds, further, that the weight of a seedling of maize approximates at any moment during the early stages of germination to half that lost by the reserve store in the endosperm.

From his experiments, and those of the other authors alluded to, he concludes that alcohol is formed in the living cells of seeds at the expense of grape sugar by virtue of a normal diastasic process, which makes them approach yeast cells more closely than has been suggested by any of the experiments hitherto published. We may inquire further how far the evidence points to the probability that the molecule of sugar is split up in that way into alcohol and carbon dioxide, and that the alcohol is the nutritive part of the sugar molecule. Certainly Mazé's experiments on the submerged seeds with the plumule exposed above the water are not inconsistent with that view. Duclaux has spoken more definitely still on this point, and has said that the alcohol formed becomes a true reserve material to be used for nutriment.

We have, however, further evidence that to some plants, at all events, alcohol is a food. Laborde has published some researches conducted upon a fungus, *Eurotiopsis Gayoni*, which point unmistakably to this conclusion. He cultivated it in a solution containing only the mineral constituents of Rawlin's fluid and a certain percentage of alcohol, usually from 4 to 5 per cent. The plant grew well, forming little circular patches of mycelium, which enlarged radially as the growth progressed. The mycelium became very dense in the centre of the patches, and the fungus evidently thrived well. As it grew the alcohol slowly disappeared, the rate being about equal to that of sugar in a similar culture in which this substance replaced the alcohol. The mycelium in some experiments was cultivated quite from the spores. Eurotiopsis is a fungus which has the power of setting up alcoholic fermentation in saccharine solutions. When cultivated in these, alcohol is accordingly produced, and subsequently used, but the growth of the mould is not so easy under these conditions as when the alcohol is supplied to it at the outset.

Duclaux has shown that in the case of another fungus, the well-known *Aspergillus niger*, though alcohol kills it while it is in course of germination from the spore, it can utilise for nutrition 6·8 per cent. when it becomes adult, continuing to grow, and putting out aërial hyphæ. Eurotiopsis is more pronounced in its liking for alcohol, for it thrives in a mixture containing 10 per cent.; even if submerged entirely it continues to grow and flourish in an 8 per cent. solution.

The peculiarity relates only to ethyl alcohol; methyl alcohol will serve as a nutritive medium for only a little time, sufficient only for the commencing development of the spores into a mycelium and disappearing very slowly from the culture fluid. The higher alcohols, propyl, butyl and amyl, not only give no nourishment, but are poisonous to spores. A very small trace of any of them can be used by the adult mould.

Laborde claims to have established as the result of his investigations that Eurotiopsis normally makes alcohol from the sugar to nourish itself with it, just as yeast makes invert sugar from cane sugar because it is the nutritive material it likes best. The enzyme zymase is present in the fungus and plays the part of an alimentary enzyme. Its consumption lasts twice as long as that of a corresponding weight of glucose; it can serve twice as long for the nutrition of the same weight of plant.

These remarkable results lead us to the consideration of the mode in which the carbohydrates, and particularly the sugars, are assimilated by the plant. We have held the view that the sugar molecule is capable of entering with little if any alteration into that of protoplasm. We have found no direct evidence bearing upon its fate. It is possible to detect sugar in the axis of a plant till quite near its growing point. Then the reaction ceases to be obtainable, and we know that assimilation is taking place. But we have still to investigate the steps, no very easy problem to undertake. May it possibly be that it is the alcohol moiety of the sugar which the protoplasm takes up, part of the carbon dioxide evolved by the growing organ being an expression, not of respiration, but of a fermentation preliminary to assimilation?

But I feel I have dealt at sufficient length with this question. I pass, therefore, to consider briefly another nutrition problem of a rather different kind. The germination of seeds is a question that might be thought to have been fairly settled by the investigations of the latter half of the last century. We have come to the conception of the seed as fundamentally a young embryo lying quiescent within its testa, and provided with a store of nourishment deposited either within its own substance or lying round it in the tissues vaguely named endosperm or perisperm. The nourishment has been held to be practically ready for its use, needing only a certain amount of enzyme action to be applied to it to convert the food store from the reserve to the nutritive condition. We have recognised here starch, proteids and glucosides, and have ascertained that the embryo can furnish the appropriate enzymes for their digestion. Each reserve store has apparently been quite independent of the rest, and the embryo has had control of the whole.

Certain considerations, however, lead us to the view that for albuminous seeds at any rate this mode of looking at the matter is no longer satisfactory. We may first ask how far the embryo is the controlling factor in the digestion. Putting the matter in another form, is the influence of the parent plant lost when a stable store of food has been provided for the offspring, and does it leave its utilisation entirely to the latter? Is the gametophyte prothallus merely to become a dead or inactive structure as soon as it has developed its young sporophyte, or may its influence extend for the longer period of germination? There are many reasons for thinking this is the case. Indeed, the view has been put forward by some observers at intervals for some years. Gris claimed to have shown it in 1864; but it was opposed by Sachs, who said that the enzymes which cause decompositions in the reserve materials are always formed in the young plant or embryo and are excreted by the latter into the endosperm. Some careful experiments on the point were conducted by Van Tieghem and were published by him in 1877. His work was carried out on the seeds of the castor-oil plant. He deprived the seeds of their embryos and exposed them for some weeks on damp moss to a temperature of 25-30° C. After several days of this exposure, he found the isolated endosperms were growing considerably, and at the end of a month they had doubled their dimensions. In the interior of the cells he found the aleurone grains to be gradually dissolving, and the oily matter to be diminishing, though slowly. The dissolution extended throughout the mass of the endosperm, and was not especially prominent in the side that had been nearest to the cotyledons. He noted, too, that though starch did not normally appear in the germinating endosperm, under the condition of non-removal of the products of the decomposition, it did appear in the cells in the form of small grains, though not till after several days had elapsed. Van Tieghem also observed that the progress of the decompositions could be arrested and the endosperms made to reassume a quiescent condition, and that then the aleurone grains again became formed, though in less quantity than before.

In some experiments on Ricinus which I carried out in 1889, I found much the same sequence of events as Van Tieghem had described. The endosperm unquestionably became the seat of a renewed metabolism, in the course of which many interactions between the various reserve materials became noticeable. It was remarkable that the activity of this metabolism was much more pronounced when the embryo or parts of it were left in contact with the endosperms.

An observation of a similar character has been made by Haberlandt and by Brown and Morris in the case of the seeds of grasses. The conversion of the reserve cellulose of barley grains has been shown by these observers to be the result of the action of an enzyme *cytase*, which is secreted largely by the so-called aleurone layer, which is found surrounding the endosperm, immediately underneath the testa.

Recently my own work has been bearing on this question, particularly as regards the behaviour of the seeds of Ricinus during germination. The reserves of this seed are mainly composed of oil and aleurone grains, hardly a trace of carbohydrates being present. At the onset of germination there is a remarkable appearance of both cane sugar and glucose, which increase as the oil diminishes. The old view advanced to explain this fact has been the transformation of the oil directly into the sugars or one of them, a theory which it was difficult to reconcile with the chemical possibilities of oil. I have found that side by side with the appearance of the sugar we have also the formation of a considerable quantity of lecithin, a fatty body containing nitrogen and phosphorus. The seed contains a comparatively large amount of phosphorus in the form of the well-known globoids of the aleurone grain, a double phosphate of calcium and magnesium. The occurrence of this body points to a considerable interaction of various substances existing in the seeds, the phosphorus apparently coming from the globoids and the nitrogen from the proteids. Instead, therefore, of the fat being transformed into sugar, it seems certain that a very considerable metabolism is set up, in which the very constituents of the endosperm interact very freely together. I am informed by Mr. Biffin, who has investigated the histological changes accompanying the germination, that the protoplasm of the endosperm cells appears to increase in amount very greatly during the early stages. The observations suggest a very vigorous resumption of metabolic activity by the cells of the endosperm, in the course of which the various reserves are brought into relation with the living substance of the cells and a number of new products are formed to minister to the nutrition of the growing embryo. The formation of the sugars may more probably be referred to the renewed activity of the protoplasm of the parent gametophyte than to a direct transformation of the fat under the influence of the embryo. Further researches upon a large variety of seeds appear necessary to give us a true idea of the chemical processes of germination. What now appears probable in the case of fatty seeds may prove to be true also in the case of those which have other varieties of reserve material.

I have already alluded to the problems concerning the electrical phenomena presented by the plant at rest and during activity. Very little work has so far been done in this direction, and our knowledge of the subject is materially less than that concerning similar phenomena in muscle and nerve. Still a beginning has been made, and we have observations on record due to Waller and to Bose which are of the greatest interest, not only because they show a great correspondence in behaviour between animal and vegetable structures, but on account of their possible importance in determining the character of many of the metabolic processes and the forces at work in the tissues.

Some very striking results were only a few months ago published by Bose on the electric response in ordinary plants to mechanical stimulation. He arranged a piece of vegetable substance, such as the petiole of the horse-chestnut, or the root of a carrot or a radish, so that it was connected with a galvanometer by two non-polarisable electrodes. The uninjured tissue gave little or no evidence of the existence of electrical currents; but if a small area of its surface was killed by a burn or the application of a few drops of strong potash, a current was observed to flow in the stalk from the injured to the uninjured area, just as is the case in animal tissue. The potential difference in a typical experiment amounted to 0·12 volt. The tissue was then stimulated, either by tapping or by a torsion through a certain angle, and at once a negative variation or current of action was indicated, the potential difference being decreased by 0·026 volt. Very soon after the cessation of the stimulus, the tissue recovered and the current of rest flowed as before. Bose's investigations extended considerably beyond this point, and established a very close similarity in behaviour between the vegetable substance and the nerves of animals. Summation effects were observed, and fatigue effects demonstrated, while it was definitely shown that the responses were physiological. They ceased entirely as soon as the piece of tissue was killed by heating.

This remarkable demonstration of similar electrical properties to those possessed by nerve strengthens very greatly the view of the conduction of stimuli in the plant by means of the protoplasmic threads which have been demonstrated by Gardiner and others to exist throughout the plant, uniting cell to cell into one coherent whole.

Much remains to be done in this field; indeed, not more than a beginning has been made. The electrical accompaniments to response to stimuli have been investigated by Burdon Sanderson in the case of Dionæa, but many other instances are still awaiting examination. The peculiar phenomena of electrotonus and their relation to stimulus have so far only been observed in animals.

These observations strengthen considerably the view of the identical nature of animal and vegetable protoplasm which has in recent years come into prominence, and which is receiving more and more support in all directions.

These electrical currents, following mechanical action, which no doubt is accompanied by chemical change, make us ask whether electrical phenomena do not in all probability accompany the slow chemical actions which we call metabolism. The view that electrical energy is concerned in the processes of photosynthesis, suggested in an earlier part of this Address, is certainly not weakened by a consideration of these phenomena.

The probability of the transmission of stimuli through vegetable tissue along the protoplasmic threads, extending from cell to cell, has been supported during the last year or two by some remarkable observations claimed to have been made by Nemec on certain roots and other organs. He says he has succeeded in demonstrating a continuous fibrillar structure in the protoplasm of the cells, fibrils passing along it in a longitudinal direction and apparently connecting the protoplasm of a longitudinal series of cells into a conducting chain. These conducting strands extend between the sensitive region—*e.g.* the tip of the root—and the region which is growing, and which is caused by the stimulus to curve. Nemec says that these conducting strands can be made evident by the use of appropriate staining reagents. They vary in number and position, but appear to be confined to sensitive and motile organs.

It is clear that the matter cannot rest where it is. The statements made by Nemec call for investigation by both histological and physiological methods. It is possible that appropriate reagents may lead to the recognition of structure in what has been hitherto regarded as undifferentiated protoplasm.

Before concluding this Address I may call attention to the vast field opening up in connection with the pathology of plants. The work done by our predecessors has been more largely work on the morphological peculiarities of various fungi than upon the physiological changes which constitute pathology, properly so called. It is only recently that attention has been given to the broad questions of disease in plants. Even now, however, certain advances have been made, and the direction of research is taking shape. In the science of pathology, little in recent years has been so fascinating as the question of immunity against the attacks of certain diseases, either hereditary or acquired. It has been bound up with the very large question of toxins and their attenuation, their opposites, the antitoxins and matters of a similar nature.

Great results have been obtained in human pathology, with which it is not for me to deal. I mention them here because we are face to face with the possibility of treating some of the diseases of plants in a similar way, and perhaps on the threshold of very far-reaching discoveries.

I may call attention to the discoveries of Ray and of Beauverie upon the general question of plant infection and especially upon a disease set up by a fungus known as *Botrytis cinerea*, which attacks grapes, begonias and other plants. The fungus exists in three forms, one of which is a harmless saprophyte, another a destructive parasite and a third intermediate between the two. The first is a very common fungus, developing on decaying plants and bearing ordinary gonidia or spores. The second is completely filamentous and bears no reproductive

organs. It is produced when the air is heavily charged with moisture and the temperature high, conditions of common occurrence in forcing houses. The third is an attenuated form intermediate between the other two. It bears gonidia like those of the first, and in addition others which germinate without falling off the parent plant and elongate into long threads. Many plants can bear the invasion of this plant without suffering greatly, though it cannot be called harmless. It occurs chiefly when a high temperature is associated with a considerable amount of moisture in the air.

It is not difficult to cultivate this attenuated form of the Botrytis in sterilised soil. Beauverie describes one experiment made with it which is very striking. Damp earth was sterilised in a Petri dish of large surface, sown with spores of the Botrytis and kept at a temperature of about 16° C. After three days, the surface of the dish was covered with a loose mycelium, which bore numerous gonidiophores. The fungus was allowed to grow for some time under these conditions, and the infected earth was then transferred to fresh pots in which were placed cuttings of begonias. The plants grew well and were not sensibly affected by the presence of the fungus in the substratum or in its surface. Placed subsequently in conditions which were eminently suitable to the development of the parasitic form, they resisted its action perfectly, though control plants which had not been cultivated in the ground infected by the attenuated form were killed very quickly. From their experiments the authors claim to have shown that the form of *Botrytis cinerea* intermediate between the gonidial and the sterile form can make plants immune to the attacks of the latter.

Researches of a somewhat kindred nature dealing with the infection of particular plants by specific fungi have been communicated recently to this Section by Prof. Marshall Ward in his paper read last year on the Bromes and their brown rust. They brought to light many very important facts connected with the question of adaptive parasitism and immunity. Few questions in vegetable physiology can compare in economic importance with these when we think of their possible development in relation to agriculture.

I have now somewhat hurriedly surveyed certain parts of the field of vegetable physiology. It has been impossible in an Address like this to do more than indicate what seem to me some of the more important problems awaiting investigation. May we hope that all such work will be vigorously conducted, but that the conclusions reached will be scrutinised with the greatest care and subjected to repeated examination? Great hindrances to the advance of the science resulted from dogmatic assertions made by eminent men in the past, their personal influence having led to their conclusions, not altogether accurate, being nevertheless almost universally accepted. Many years subsequently these conclusions have needed re-examination, the result being the destruction of a whole fabric that had been reared upon this unworthy foundation. I may close, as I began, by an appeal to the younger school of botanists to take some of this work in hand, and by assiduous and critical experiment and observation to contribute to the solution of the problems pressing upon us in this field.

SECTION L.

EDUCATIONAL SCIENCE.

Opening Address by Prof. Henry E. Armstrong, LL.D., Ph.D., V.P.R.S., President of the Section.

The last meeting of the British Association at Belfast was presided over by Prof. Tyndall, one of whose most memorable discourses was that delivered at Liverpool in 1870 on "The Scientific Use of the Imagination." In the course of his Address, the President could point out that "science had already to some extent leavened the world," and abundant proof has since been given that he was right in claiming that "it will leaven it more and more." Nevertheless, if we consider the leavening effect which science has had on the public mind, it is impossible to deny that progress is being made in this direction at a woefully slow rate, in no way proportionate to the growth of knowledge or to the recognised usefulness of the many discoveries which are the outcome of scientific investigation. Science is still treated by society as a rich *parvenu* all the world over, and is at most invited to its feasts, but not incorporated, as it should be, with the domestic life of the people.

Complaint has long been rife that the British are indifferent as a people even to things which are of manifest importance, and which as a nation of business men they might be expected to value. It would certainly seem that we are all too forgetful of Tyndall's warning that "every system which would escape the fate of an organism too rigid to adjust itself to its environment must be plastic to the extent that the growth of knowledge demands." As our President said a full quarter of a century ago, "when this truth has been thoroughly taken in, rigidity will be relaxed, things not deemed essential will be dropped, and elements now rejected will be assimilated. The lifting of the life is the essential point, and as long as dogmatism, fanaticism and intolerance are kept out, various modes of leverage may be employed to raise life to a higher level."

But how are we to become plastic to the extent that the growth of knowledge demands, in order that rigidity may be relaxed, that conservatism may give way to a wise spirit of advance? Probably there is no more important question the nation can ask at the present time; for that we are wanting in plasticity is proved to demonstration. Does not the shade of our former President stand before us and solemnly give answer: "By the cultivation and exercise of imaginative power—by the scientific use of the imagination"; for in these days are we not indeed a people "of little faith"? There would seem, in fact, to be clear evidence, if not of destruction, at least of impairment, of imaginative power under modern conditions—that the tendency of education is to kill rather than to develop the very power on which the progress of the world depends. A dearth of imaginative power is strikingly apparent in art, in literature, in music, in science, in public taste generally, the prevailing tendency being to imitate rather than to originate and individualise. Commentators and critics of sorts abound, but these rarely display any catholicity of judgment. Leaders are few and far to seek. The prevailing policy is that of the party in power, and more often than not of a caucus behind it—not the policy which on broad general grounds is the most desirable; in fact, little attempt is made to discover in any scientific manner what would be the really wise policy to pursue. Nothing could illustrate this better than the state of chaos into which affairs educational are plunged at the present time. Those who dare to differ or offer advice are looked at askance, and always with jealous eyes; and too often everything is done to block the way of the reformer, not from any base motive, but as a rule from sheer inability to appreciate what is proposed—from sheer lack of imaginative power. Necessarily, as the conditions of civilisation become more complex, the tendency to accept and follow must become greater, and self-satisfaction more and more complete and general; but unless effective means be taken to counteract such a tendency, decay is inevitable.

The phrase "creatures of habit" is familiar to us all; few will deny that we are seldom otherwise than creatures of habit and that plasticity of mind is a rare attitude. But the growth of knowledge is taking place at such a compound interest rate that a high degree of plasticity is essential if we are to avail ourselves thereof. We were formerly accounted a nation of shopkeepers—of clever shopkeepers—but now the title is passing from us to the Germans and Americans, because they are more alive than we are to the fact that in these days it is necessary both to organise and to be alive to every opportunity. If we would put money in our purse in future, it will be necessary to put imagination into our affairs, so that we may be far more ready to act than we have been of late years.

And not only is knowledge increasing, but our responsibilities are daily becoming heavier and heavier. In the minds of thinking men at the present time, the burden of empire our nation bears is of appalling magnitude; the men who have imaginative power are aghast at the flippant unconsciousness of responsibility manifest in the public at large, and even in the majority of our statesmen and politicians. It is widely felt that a deeper sense of responsibility must be induced among us if we are to maintain our heritage intact—if we are to remain worthy to play the great part for which by an inscrutable ordinance we find ourselves cast at the very commencement of a new century. Nothing is so sure as that if we cannot show ourselves to be worthy we shall not long be allowed to play the part: jealousy confronts us on all sides; and we have learnt that the struggle for existence is Nature's first law, against which philanthropy is powerless so long as it be not universal—a contingency which is not even remotely possible. It is little short of remarkable that we should be able to go so far as we

do in securing the services of able men to conduct our affairs generally; but we cannot be too mindful of the duty incumbent upon us of developing the store of ability latent in the nation, and above all of maintaining intact our heritage of individuality.

The call to organise the forces of our empire is imperative, but we do not heed it in any proper manner. For many years past we have rarely refused to treat with utmost consideration the representations of those who have dwelt on the importance of our Navy. One of the most highly respected men in the country at the present day is our gifted American cousin, Captain Mahan, on account of the way in which he has exercised his powers of imaginative insight and taught us to understand our achievements at sea, to appreciate the true meaning and value of sea power. We need a Mahan to discuss the larger issues of national defence through education, to teach the nation the true meaning and value of education. The Ship of State is of vastly greater consequence than the mere Navy, and yet those who direct attention to the insufficient character of its armament are scarce listened to; not the slightest effort is made to secure for it a scientifically adjusted and organically complete machinery for the effective administration and working of all its departments; the drill of its crew is woefully incomplete; what is worse, there is a terrible absence of organisation and discipline, a terrible absence of willingness, little, if any, desire among those who are charged with its care to cooperate, and the consequences of neglect are not immediately obvious. In war we appreciate the effects suddenly: a long list of killed and wounded brings its meaning home to us at once; and we know that we must pay the penalty of defeat forthwith. The indemnity exacted can be expressed as a lump sum. The battle of life is waged in a less obtrusive way, the killed and maimed are not scheduled in any regular manner, and so it escapes our notice that in reality the carnage is awful, that few, if any, escape without severe wounds, that defeat is constant and yet often dealt so silently and imperceptibly that it excites little comment. But we know that vastly more than is done might be done to alleviate if not to prevent suffering, and even to give charm to life where at present there is but pain, if only our efforts could be organised. If we reflect on the bareness of the life lived by the majority, on the debasing conditions under which very many are placed, on the terrible evils consequent on indulgence in drink, surely we must agree with Tyndall that the essential point is to raise life to a higher level, to elevate the general tone of thought, and that it is our duty to consider more seriously than we have done hitherto what use can be made of the forces at our disposal for the purpose.

If we will but picture to ourselves how most of our difficulties, and especially our slow advance, are consequences of lack of imaginative power, or perhaps rather of failure to exert the power which, though latent in most of us, is not sufficiently called into being by practice; if we will but consider how much of our success has been due to the exercise of imaginative power, we may be led to propound a fruitful theory of education, a theoretical basis on which a sound educational structure may be reared. It has been well said by Carlyle "that all that man does and brings to pass is the vesture of a thought." In fact, the illustrations which may be given of the value of theoretical conceptions, of imaginative power, are innumerable. Taking recent events, if we consider the success achieved by the late Mr. Rhodes, the narrow-sighted will say he was a practical man; a man who did things and led others to do. Those with broader views recognise that at heart Mr. Rhodes was a theorist, an idealist, a man of imagination, and hence his success. And men such as Lord Roberts and Lord Kitchener, whose immense services to the nation have been so universally admitted of late, are not merely practical soldiers of experience, but men gifted with powers of insight and imagination; men able to apply theory to practice. Some of those who were unsuccessful in the late campaign are currently reported to have gone out to South Africa openly deriding science, and it will be well if the lesson taught by their failure be not disregarded by their colleagues. The importance of the part played by theory in science cannot be exaggerated. We have only to think of the influence exercised by the Newtonian theory of Gravitation, by the Daltonian theory of Atoms, by Faraday's conception of Lines of Force, by the Wave theory in its varied applications, by the Darwinian theory of Evolution; we have only to think of the way in which the reflections of one weak man indited at his study-table in a secluded Kentish village have changed the tone of thought of the civilised world. Such theories are the very foundations of science; whilst facts are the building stones, theories furnish the design, and it is the interpretation of facts in the light of theory and the considered application of theory to practice that constitute true science. The marvellous development of scientific activity during the past century has been consequent on the establishment of fruitful theories. If teachers generally would pay more attention to theory their teaching would doubtless be more fruitful of results; facts they know in plenty, but they lack training in the considered use of facts. False prophets among us have long taught the narrow doctrine that practice is superior to theory, and we pretend to believe in it. That the belief is founded on misconception may safely be contended, however; the two go together and are inseparable. It is true that we have enjoyed the reputation of being a practical people, and have been accustomed to take no little pride in the circumstances, and to scoff somewhat at theory, but behind our practice in the past there was a large measure of imaginative power, of theoretical insight; in fact, we were successful because we were innately possessed of considerable power of overseeing difficulties, of grasping an issue, of brushing aside unessential details and going straight to the point; in other words, of being practical. We are ceasing to be practical because modern practice is based on a larger measure of theory, and our schools are paying no proper attention to the development of imaginative power or to giving training in the use of theory as the interpreter of facts; didactic and dogmatic teaching are producing the result which infallibly follows in their wake—sterility of intellect.

Mr. Francis Darwin, in his Reminiscences of his father, tells us that "he often said that no one could be a good observer unless he was an active theoriser." And he goes on to say: "This brings me back to what I said about his instinct for arresting exceptions: it was though he were charged with theorising power ready to flow into any channel on the slightest disturbance, so that no fact, however small, could avoid releasing a stream of theory, *and thus the fact became magnified into importance*. In this way it naturally happened that many untenable theories occurred to him; but fortunately his richness of imagination was equalled by his power of judging and condensing the thoughts that occurred to him. He was just to his theories and did not condemn them unheard; and so it happened that he was willing to test what would seem to most people not at all worth testing."

In his Autobiography, Darwin remarks:—"I have steadily endeavoured to keep my mind free so as to give up any hypothesis, however much beloved (*and I cannot resist forming one on every subject*), as soon as facts are shown to be opposed to it." The italics in these passages are mine.

Our system of education has no proper theoretical basis. Educators have ceased to be practical because they have failed to keep pace with the march of discovery, the theoretical basis underlying their profession having been enlarged so rapidly and to such an extent that it is beyond their power to grasp its problems. The priesthood of the craft are, in fact, possessed by the spirit of narrow parochialism, and upholders of an all too rigid creed, being lineal descendants of a privileged class—"the knowledge caste," to use Thring's expression—whose functions were far more limited than are those which must now be discharged by teachers if teaching is to be given which will serve as an efficient preparation for life under modern conditions. They enlarge *ad nauseam* on the superiority of literary and especially of classical training, forgetting that their preference for classics is but the survival of a practice and that their arguments in defence of a literary system are but preconceived opinions. Being incapable of appreciating the arguments used on the other side, it is unlikely that they will ever be able to admit their force.

So long as the forces of Nature were not tamed to the service of man, they could be neglected; sanitary sins were alone found out and punished with unsparing severity. But now it is otherwise. To succeed in competition with others we must be able to avail ourselves of every opportunity; and wide understanding is demanded of us. Moreover, the growth of knowledge has induced severe mental hunger, and the feeling that the dainty dishes provided by Nature should be in no selfish manner restricted to the few is a growing one; altruism is a growing force. We feel that we are called upon to counteract the evils arising from the growth of our cities; from the concentration of workers in large bodies; from the minute subdivision of labour; from the depressing conditions under which the masses daily

toil. To provide relief and healthy occupation for leisure hours, and to secure that vacuity of mind and pettiness of motive shall no longer be the sore affliction they now are, we must take all the requirements into consideration and define with utmost minuteness the task in hand; broader and higher ideals than those now prevailing must be established and practical requirements must be met. To secure the right attitude of mind for this task will not be easy. Few realise, few know, how signal is our failure to appreciate our power, how deplorably we neglect our opportunities. The bareness of the fare we provide is nothing less than shameful in view of the rich possibilities which lie ready to hand. In saying that

> A primrose by a river's brim,
> A yellow primrose was to him
> And it was nothing more,

the poet has well pictured our average attitude towards our surroundings. To the majority, indeed, a primrose is scarcely a primrose; it is unseen. It is little short of impossible to account for our callous disregard of the wondrous beauty of the multitudinous objects displayed in Nature's realm, our willingness to remain ignorant of the meaning of the mysterious changes which are ever happening before our eyes. That familiarity should breed such contempt is passing strange; but how great the guilt in these days of those who allow the contempt to grow up, knowing as they must that the ignorance is easy to dispel, knowing also that those versed in the mysteries have ever sought to lay bare all that is within their ken. The failure on the part of those who have the charge of education to make a scientific use of the imagination is nothing short of complete; there is nothing to show that the imagination is ever called into play.

Surely it were time to make some real effort to imbue all with a proper understanding of their surroundings, to create in all minds a higher and reverent interest in life.

It is a sad reflection and a grievous blot on our civilisation that our spiritual advisers are mostly so little regardful, so destitute of understanding, of the works of that Omnipotent Power which all must recognise and humbly submit to, whether or no allegiance be acknowledged in doctrinal terms; they before all others should be prepared to consider their inmost meaning and to direct attention to their wondrous mechanism. We indeed need to send forth a new mission charged with the holy duty of enabling man to appreciate and acknowledge the beauty of the universe, as well as of preparing him to be a thoroughly effective worker, thus fitting him for the true, unselfish and reverent enjoyment of life. To use the apt words of the Master, quoted by the Poet at the Breakfast-table: "If for the Fall of man, science comes to substitute the Rise of man, it means the utter disintegration of all the spiritual pessimisms which have been like a spasm in the heart and a cramp in the intellect of men for so many centuries."

If we can but make sweet use of our present adversity, though we may not be exempt from public haunt but live even in crowded cities, we shall unquestionably soon find

> . . . tongues in trees, books in the babbling brooks,
> Sermons in stones and *good in every thing.*

The wonderful prescience of our great poet is nowhere more clearly displayed than in these lines, and it is more than surprising that although generations have been charmed by the music of the words, so little has been done to realise their meaning or to give them a meaning in the minds of the majority.

It is but a question of attitude, for, as Carlyle somewhere says, "so soon as men get to discern the importance of a thing they do infallibly set about arranging it, facilitating it, forwarding it, and rest not till in some approximate degree they have accomplished that."

Unfortunately, there are all too many things of which we fail, through our faulty education, to discern the importance, but which a little understanding, the exercise of some slight imaginative power, would enable us to appreciate. I will take the word *Energy* as an example. No word in the English language carries more meaning to those versed in the principles of physical science, and yet how narrow its connotation in the minds of the uninstructed majority. As a guide of practical conduct, no word is of greater significance, and if its true implication fully seized us the word would ever rankle in our ears and serve to remind us of the maxim "Waste not, want not." In Great Britain we are using up our coal stores at the rate of over two hundred millions of tons per annum. Used at such a rate, the supply cannot last many generations; whence will our children derive their supplies of energy? Energy cannot be created. When we have squandered the wealth funded on our earth by the sun in æons past, we must fall back on the modicum we can snatch from the daily allowance the glowing orb dispenses, for his largess will for the most part be wasted and will be very difficult to garner in our country, sun mills, wind mills and falling water being but irregular and ill-disciplined servants, trees growing but slowly. In all civilised countries the same criminal waste of fuel—of energy—is going on; but although we recognise that individual men have no right to live beyond their means and have little pity for bankrupts, no corresponding feeling exists on the subject of collective squandering. The spendthrift is regarded with equanimity, because he but distributes his gold among the many—so that the many gain while he alone is the loser—but the energy of fuel is spent irrecoverably, and all waste is not merely apparent, but real. To waste fuel is to court criminal bankruptcy; but to how many does it occur that we are all parties to such a crime? Does any schoolmaster or schoolmistress call attention to the fact? How many heads of schools could even write a respectable essay on such a topic? When I have suggested "A piece of coal" as the subject for a scholarship examination essay, I have actually been told by literary critics that you have no right to ask for knowledge of facts in a schoolboy's essay, the object being but to find out to what extent he can "gas" in flowing periods! A scuttle full of coal excites no emotions in the literary mind; it should be one to call up harrowing visions, as well as a vista of memories extending far back into the ages of time, for in no other stone can we find a more wonderful sermon.

To descend to the ordinary level, how many householders ever take into consideration the wicked waste of fuel which goes on in their establishments? how many are really thrifty in the use of fuel? I never see a "Kitchener," or hear it roar, but I shudder. The prevention of smoke is of no consequence in comparison with the prevention of the waste of fuel. Even when every care is taken the waste is very great—simply because our means of utilising the energy of fuel are so imperfect. The best steam engine can recover for us but very few per cent. of the energy stored up in the coal which is burnt in its boiler fire. If we could succeed in burning fuel electrically—in directly converting the latent energy into electricity—it is conceivable that the engine might be of nearly theoretical efficiency. But what imaginative power must be exercised to secure such a result! Cannot we in some measure hasten the time of such discovery? Prof. Perry not long ago had the temerity to direct attention anew to the subject in NATURE, and made what many practical people will consider the impossible suggestion of a wildly imaginative, irresponsible Irishman—that a round million or so should be devoted to systematic experiments, with the object of discovering means of increasing the efficiency of our engines. If we consider what is the cost of a modern battleship; if we consider what has been spent on the war in South Africa; if we consider the extent to which the value of the fuel at our disposal would be increased if we could only double the efficiency of our engines and of our stoves, Prof. Perry's proposal cannot be regarded as otherwise than modest and sensible. But what is of real importance is the implied suggestion that the subject should be seriously inquired into at national expense. It must, and at no distant date, be admitted that our fuel stores are national assets over which there should be some national control.

I may take Food as another subject of which we fail to discern the importance, and which is outside the schoolmaster's ken, although teachers have stomachs as well as other men, and boys in particular are believed to take some interest in the existence of that organ. It is but a variant on that of energy, as the food we take is mainly of value as the source of the energy we expend—as fuel, comparatively little being required for the construction and repair of the bodily machinery.

> . . . God has made
> This world a strife of atoms and of spheres;
> With every breath I sigh myself away
> And take my tribute from the wandering wind
> To fan the flame of life's consuming fire.
>
> *Oliver Wendell Holmes.*

How many will appreciate this pregnant passage; in how many schools is instruction given which would make it possible to recognise its beauty and completeness as a statement of the philosophy of the respiratory process? Our ignorance of ourselves and of the functions of food is indeed phenomenal. Life involves the unceasing occurrence of a series of changes for the

most part chemical. If the proper study of man be man—as the highest dignitary of our Church some time ago asserted it was—the ordinary person would be prone to assume that those in charge of education would so direct studies as to give man some interest in his own wonderful mechanism; instead they almost uniformly direct that true "culture" consists in knowing what he has thought and written of himself in classic tongues, in ages gone by before the slightest vestige of understanding of the phenomena of life had been obtained. And we moderns calmly suffer this, and at the same time wonder at the way in which primitive peoples allow their medicine men and wizards to dominate them. Taking into account what is known, ours perhaps is relatively a deeper savagery than is that of most untutored races; our educational priesthood are for the most part never trained to a knowledge of the mysteries and deny admission through ignorance rather than wilfully.

From food to the preparation of food is an easy step—in point of fact, the knowledge how to prepare food properly is of far more importance than any knowledge of what food is and does, as on it depends much of the happiness and health of mankind. Cooking is a branch of applied chemistry. We live in a scientific age—an age of knowingness. We might therefore expect that our girls at least would be so trained at school that with little effort they could become knowing cooks. I am not aware that the authorities who lay down the regulations for University Locals or similar examinations have allowed any such vulgar considerations to guide them in drafting their examination schemes: niceties of grammatical construction, recondite problems in Geography and History, the views of an ancient philosopher who gave himself up to angle worship, are alone thought of on such occasions; and yet there are times, it is said, when these august persons deign to take some notice of culinary efforts, and they cannot be unaware that cookery is a subject of some importance, which might well at least be led up to at school. To justify my reference to the subject, let me read a passage from "An Address on Education," delivered, not by a narrow-minded Goth who is so lost to reason as to doubt the sufficiency of an exclusively literary training as a preparation for life, but by a classic, the Headmaster of a great public school, Thring of Uppingham, in speaking of the Higher Education of Women at St. Albans in 1886.

"We English are proud of our homes. We sing songs about them, we write on them; in fact, we are very justly *proud of our homes*. Has it ever entered your minds that home to the great majority in a very large degree, and to all in some degree, is but a loftier name for cookery? In a cottage good cookery means economy, luxury, health, comfort, love. . . . Cookery to the vast majority of mankind means home, and when the weary worker comes back from work wanting to refit, cookery alone can turn him out fit for work again. From this point of view home is cookery."

Cookery is certainly a subject of which those in charge of education have not yet in any way discerned the importance. Our cooks are inferior and wasteful simply because they fail to exercise sufficient imaginative power. If we wish to make good cooks of our girls, we must teach them to think for themselves and to be imaginative—to make a scientific use of their imagination; they will then come to see that the subject is a vastly interesting one, full of opportunity for research. The kitchen, of all places, is the one, in fact, in which the heuristic method should most flourish.

Could we find tongues in trees we should doubtless find them eloquent on the subject of food supply, and far more delicate in their tastes than any mortals. But how many of us, looking at a green leaf, can in any way call to mind the wonderful mechanism which enables the plant to secure the main bulk of its solid substance from the fleeting stores in the circumambient atmosphere; or the manner in which it is dependent on light; or its mineral needs; or its great need of water and its wonderful transpiratory activity? And yet the chief industry of the world is agriculture—the feeding and tending of plants. At least those who lead a rural life should have their imagination excited on such subjects at school; it is even possible that much of the asserted dulness of a country life might pass away if an interest in plant activity were properly cultivated. And schoolmasters might even find comfort in the reflection that, as Messrs. Brown and Escombe have recently shown, the translocation of the material first formed in the leaves, metabolism and growth are become so intimately correlated that the perfect working of the entire plant is only possible in an atmosphere containing the normal amount of three parts of carbon dioxide per ten thousand; they might recognise in the plant an organism after their own heart, with ripened conservative instincts, and unwilling to accept any other than the limited diet long favoured by the craft.

In these days, not only the obvious, but also the microscopic forms of life claim attention, and it is imperative that all should be at least aware of their existence and mindful of the deadly power that some of them exercise. All should be able to read with intelligence the wonderful story of the beneficent labours of the great Pasteur—a true saviour of mankind—and appreciate their value. The lessons of sanitary science will never be properly brought home to us and heeded in daily life until a more direct intimacy with micro-organisms is encouraged at school.

And whether or no there be "good in everything," children must at least be encouraged to seek it; to use their eyes always, and to reflect on what they see. A proper use will be made of leisure and of holidays when they are so trained, and even "Days in the Country" will be days of enjoyment and peace for all, never of mere vacuous wanderings, let alone of wanton destruction, and will leave no memories of broken glass and waste paper behind them. And in the end the national drink bill may be considerably diminished if Shakespeare's words come to have some slight meaning for all.

Let us consider what we can do to further this most desirable end. Section L is in advance of the times, being concerned with a non-existent science—the Science of Education. The science will come into existence only when a rational theory of education is developed and applied; but it is clearly on the very eve of coming into existence, otherwise the section could not have been established; and we may contribute much to its development.

Surely, the primary article of our creed will be that—as Thring has said—"the whole human being is the teacher's care," for all must admit that the faculties generally should be cultivated and educated. At present we make the fundamental mistake of disregarding this truth, but there is evidence that sounder views are beginning to prevail. It is very noteworthy, for example, that in the recent report of the Committee on Military Education it is laid down that *five* subjects are to be regarded as *necessary* elements of a sound general education, viz. English, Mathematics, a Modern language, Latin and Experimental Science. Moreover, it is recognised that each of these subjects has a peculiar educational value of its own. Such a conclusion takes the breath away; indeed, it is almost beyond belief that Headmasters of Public Schools could commit their brethren by attaching their names to a report containing such a paragraph as the following:—

"The fifth subject, which may be considered as an essential part of a sound general education, is Experimental Science, that is to say, the Science of Physics and Chemistry treated experimentally. As a means of mental training, and also viewed as useful knowledge, this may be considered a necessary part of the intellectual equipment of every educated man, and especially so of the officer, whose profession in all its branches is daily becoming more and more dependent on Science."

Just consider what this recommendation means; that it is now publicly admitted by high authority that *all* boys should have the opportunity given to them at school of gaining knowledge *by experience*—by actually doing things themselves, not merely by reading about them or being told about them, because this, and nothing short of this, is what is aimed at by all who advocate the introduction of Experimental Science as a necessary part of school training. The reign of the cleric as absolute monarch of the school kingdom will be at an end if such doctrine be accepted and acted upon, and there will be some chance of our regaining the reputation of being a practical people. Members of the British Association will be carried back in a dream some thirty odd years, to 1867, when a report from a Committee, consisting of the General Officers of the Association, the Trustees, the Rev. F. W. Farrar, the Rev. T. N. Hutchinson, Prof. Huxley, Mr. Joseph Payne, Prof. Tyndall and Mr. J. M. Wilson, specially appointed to consider the best method of extending Scientific Education in schools, was presented by the Council to the General Committee, and it was resolved: "That the President of the Association be requested to communicate the Report to the President of the Privy Council," &c. One among the reasons then given why general education in schools ought to include some training in science was, "as providing the best discipline in observation and collection of facts,

in the combination of inductive with deductive reasoning, and in accuracy both of thought and language." History does not record what the Privy Council did with the memorial. Had the Council been mindful of its duty to the country and paid serious attention to so weighty a representation, our present position might have been a very different one; the German and American bogies would have assumed less portentous dimensions in our eyes, and we might have found ourselves far better prepared than we were to cope with the conditions in South Africa. Accuracy of thought and language, according to the evidence given before the Committee on Military Education, are qualities in which military candidates are particularly lacking, notwithstanding the asserted value of Latin—the chief subject of study in the Public Schools—as mental discipline.

Unless we are prepared to disregard, not only all the lessons of the recent war, but also the lessons we have been receiving during years past in the wider war of commercial competition; unless we are prepared to disregard the still wider consideration that education must be an effective preparation for life and not merely for business, the findings of the Committee on Military Education must be embodied in our practice. Undoubtedly the real issue decided by the Committee was the question whether the *antecedent*, and not the technical, training of military candidates was properly conducted. In other words, *our Public School system was on its trial.* Although not referred to in so many words, this system is most effectively condemned in spirit in every line of the Report, and far more between the lines. But the Committee have merely recognised what has been known for years and years; not a single novel point is brought out—not a single novel issue is raised in their report. By making definite recommendations, however, they have lifted the subject on to a higher plane, and it is these recommendations which require the most careful consideration *and revision*; for if carried out, as they stand, there will be little improvement in our condition. The Committee have certainly done more than they were asked to do, but not more than they were bound to do. By the terms of reference they were to consider and report what changes, if any, are desirable in the system of training candidates *for the Army* at the Public Schools. Instead they have recognised that education at secondary schools has in a great measure conformed to the course generally prescribed by public professional examinations originally designed to secure the selection of candidates who had availed themselves of the advantages of a good general education; and that the State has been careful in the matter of examinations that they should be so framed as not to disqualify or hinder the unsuccessful candidate from entrance into other professions; or, in other words, that neither more nor less is to be exacted from candidates for entrance into the Army than from candidates for other professions. Consequently the requirements to be laid down for Army candidates are such as can be met from a sound general education, and in no way special. The Committee have, in fact, pronounced judgment on the subject of all others which is of greatest consequence to the nation at the moment. But they were not actually appointed for such a purpose, although they should have been, as it was to be foreseen that the major issue must be tried if the minor were to be settled. The modern spirit in education was not sufficiently represented on the Committee. Of the witnesses examined, too few had any practical acquaintance with the work of education, although a great many who could judge of its effects gave evidence; and the practical side of education was scarcely considered. Only one witness was examined on behalf of "Science," and Mathematics was unrepresented. Such being the case, it is surprising that the Committee should have gone so far in their recommendations, and a proof how overwhelming the case must be in favour of change.

Among the signs of the time showing that liberal views are coming into vogue, I may refer to the provision made in the new buildings designed by Mr. Aston Webb and Mr. Ingress Bell for Christ's Hospital School, which was removed from London in May last. The new home of this ancient foundation is situated in the county of Sussex, about four miles south-west of Horsham, and comprises an area of 1300 acres of land—meadow, arable and woodland. Nearly 600,000*l.* have been expended on the new school up to date. Provision is made for 800 boys, and together with the necessary staff, these will form a colony of some thousand persons. The school provides its own water supply, disposes of its sewage by the bacterial system on its own premises, and is lit entirely by electricity generated on the spot. Only food and clothing are derived from the outside. If senior boys, in the future, are allowed to gain some insight into the interior management and economy of such an institution, what wonderful opportunities they will enjoy! And I hope the day is not far distant when boys will learn to understand everything connected with the school in which they pass so many years of their lives. A school should be the last to deny to boys every opportunity of gaining such invaluable experience. Fortunately, Christ's Hospital School is conducted on the hostel system; the masters are therefore not charged with household cares, and have no temptation to withdraw their thoughts from the work of education. The school has no taint of commercialism about it. It will be a happy day for our country when this is true of all our schools.

The school buildings are placed nearly in the centre of the site and cover an area of about eleven acres. They are disposed along a slightly convex line facing southwards, the extremities curving gently towards the east and west respectively. The main range has a frontage of 2200 feet. At the eastern end, detached from the main range and somewhat retired, are the Infirmary and Sanatorium, which has a frontage of 500 feet. There are extensive playing fields and also a Gymnasium and Swimming Bath.

The scholastic buildings are grouped in the centre around a "Quad," 300 feet by 240 feet.

The Dining Hall, 154 feet by 56 feet, behind which are the Kitchens and subsidiary offices, is placed on the north side of the Quad. The Chapel has sole possession of the western side. The School Hall, 130 by 50 feet, is at the centre of the southern side, class rooms being provided in two buildings parallel to it, but separated by intervals of 40 feet.

The Science School faces the Chapel, filling the eastern side. The Art School and Library are arranged at right angles to it, somewhat in the background. The Science School consists of four main "laboratories," with subsidiary smaller rooms attached to each. No lecture rooms are provided, as Science is to be studied at the work bench; but each of the laboratories has a space arranged so that demonstrations may be conducted within it. The laboratories are fitted up as workshops, as well as in the ordinary way, so that boys may use tools as well as test-tubes, and the effort has been made to keep the fittings as simple as possible. Workshops for specific manual instruction will be provided in addition to the Science Schools. Experimental Science will be taught throughout the school. It will be obvious that body, mind and soul have all been cared for. Whilst due provision has been made for the intake of that energy which is so indispensable to the indulgence in mental effort as well as to the maintenance of the vital machinery, science has received recognition at the hands of the designers of the Buildings, of the Governing Body and of the Head Master in a manner heretofore unusual; it has actually been placed on an equality even with religion and with literary study, and it may be hoped that the reverent regard of the beauties and wonders of Nature gained in the Science workshops and in the surrounding country will but deepen the feelings of devotion proper to the Chapel and greatly help in lifting the life of the school to a high level. May the example not be without effect.

It has been my privilege to act as the nominee of the Royal Society of London on the Governing Body of the School during several years past, and I may be permitted to bear witness to the manner in which one and all have been mindful of the needs of the times in arranging the new buildings. I believe few Governing Bodies of Schools will do otherwise than promote advance, if properly advised. Resistance to progress comes from within the schools. The public must force the schools to reform.

Let me now return to the recommendations of the Committee on Military Education. It is to be noted that they clearly involve the recognition of two sides to education—*a literary and a practical.* I use the term practical advisedly, because it would be wrong to draw a distinction between a literary and a scientific side, as the whole of education should be scientific, and science—true knowledge—and scientific method—true method—should pervade and dominate the whole of our teaching, whatever the subject-matter; and as the object of introducing experimental science into the school is to give the scholars an opportunity of gaining their knowledge at first hand—by practical heuristic methods, as distinguished from literary didactic methods—the introduction of such discipline may be properly said to involve the recognition of a practical side.

The term practical must not be understood as the antithesis of theoretical. Practice is inseparable from theory in all true teaching, the advance from one practical step to the next being always over a bridge of theory. But if it be granted that education necessarily has two sides, it follows that the Committee on Military Education are illogical in their recommendation that Latin and Experimental Science may be treated as alternative subjects; they are but complementary, not alternative, subjects. The only possible alternative to Latin would be a subject in the literary branch—another language, in fact.

But the recommendations of the Committee are also far from satisfactory on the subject of languages. "The study of languages," they say, "forms a third main feature of a sound general education. Of these the most important, from an educational point of view, is Latin. Modern languages, though much inferior to Latin as a means of mental discipline (at least as generally taught), must none the less be regarded as an important part of a sound general education." In face of this conclusion it would have been logical to make a modern language rather than Latin the alternative to Experimental Science, but obviously the Committee dared not omit the modern language. It is true the recognition of Experimental Science and Latin as possible alternatives may be regarded as a high compliment to the latter, but it was never intended to be such; in truth it marks the recognition of the inevitable; that Latin will ere long be deposed from its high estate and intellectual freedom granted to our schools, greatly to the advantage of Latin, I believe. There is no doubt that the relative value of Latin as an educational subject is grossly exaggerated; those who dwell on its merits are rarely conversant with other subjects to a sufficient extent to be able to appreciate the effects these would produce if equally well taught. As a matter of fact, in the case of Latin the most capable teachers have been chosen to teach the most capable boys, and the results obtained have been unfairly quoted in proof of the superior value of the subject. We have yet to discover the highest value of other subjects, their depth of power as disciplinary agents having been most imperfectly sounded. And if we consider results, do not they afford proof that the belief in Latin (as taught) is misplaced? It has been the staple subject of education and has been supposed to afford the most valuable training possible in composition.[1] Nevertheless the complaint is general, and not only here but also in Germany—where Latin is far more taught and believed in—that composition is the one subject of all others which the schools do not teach. The fact is, Latin is a subject which appeals to the minority of scholars, and the time of the majority is wasted in studying it. I would give to all an opportunity of proving their aptitude in Latin and Greek, or at least some opportunity of appreciating the construction of these languages; but I am inclined to favour the proposal—made by high authority, I believe—that such studies should follow that of modern languages rather than precede it. The true study of classical languages should be reserved for the University. In any case, it is beyond question that a very large proportion of those who would make magnificent officers are incapable of learning Latin to advantage; such will in future enjoy the inestimable advantage of studying Experimental Science; but if those who take up Latin are in consequence to lose all opportunity of acquiring some power of reading the secrets of Nature and of thereby developing thought-power and mental alertness—and such must be the effect of the adoption of the recommendations of the Committee—they will prove to be of little value to the army in comparison with their colleagues whose eyes have been trained as well as their "intellect." In the course of the evidence given to the Committee, Dr. Warre expressed the view that Science would kill Latin eventually. Nothing could be more unfortunate, but the course adopted by the Committee is that most calculated to bring about such a result, as Latin is thereby put in competition with a subject which must ere long be regarded as a necessary subject of school instruction under all conditions. Latin should be made one of the optional subjects along with Greek.

In their scheme of marks for the examination, the Committee put Latin, French or German and Experimental Science on an equality by assigning 2000 marks to each; but English and Mathematics are rated at a higher value, each receiving 3000 marks. It would have been better to have assigned equal values to the several group-subjects regarded as essential to a sound general education. It should scarcely be necessary to put a premium on the proper study of a man's own language; the subject has naturally a great advantage over others. As to Mathematics, there is no doubt that this also is a subject of which the relative value as mental training has been greatly over-valued, and that the methods adopted in teaching it have been very faulty; consequently much time has been wasted and its true value has not been appreciated, as it has been made to appear unnecessarily difficult and forbidding. The evidence before the Committee against Mathematics being carried too far was very strong. Thus Captain Lee, in examining Major-General Sir C. Grove (speaking of the training at Woolwich), said (Q. 604): "There was an immense amount of pure mathematics and so forth, which one never has occasion to utilise afterwards, unless one becomes an Instructor of Cadets at Woolwich, where you teach them the same useless things you have learned yourself." This elicited from General Grove the reply: "Well, there is a strange tendency in Mathematics—I do not know why—that wherever you introduce them they encroach horribly. I am always struggling to cut down advanced mathematics." And more to the same effect. Again, Lieutenant-Colonel S. Moores, when asked whether he considered the syllabus for the entrance examinations at Woolwich and Sandhurst to be reasonable (Q. 2353), at once replied, "No, sir; Mathematics are, in my opinion, very much over-valued as a subject for Army examinations, excepting for the Royal Engineers."

After all, if reasonable standards were adopted both in Mathematics and Latin, these subjects would not create the difficulty they do in examinations at present by absorbing so much of the time in school that no proper attention can be given to subjects in reality at least of equal importance. It should be insisted that fundamentals be thoroughly taught, and by practical methods, so that the knowledge acquired may be real and usable; it is astonishing how far students may be carried in Mathematics, and how real and interesting the subject becomes, when they grasp the fact that it has a practical bearing.

While dealing with Mathematics, I cannot refrain from quoting a statement made by Captain Lee (Q. 4209), with regard to the relative values of this subject and science to military men, as the opinion he expressed is of very general application. "I think it is quite true," said Captain Lee, "that a great number of Artillery officers do go through their service without using Science, but I think they feel that any science they know proves of much more practical use to them in their profession than the Mathematics they have learned. As far as I know, in the most scientific branch of the Artillery, the Garrison Artillery, there are practically no occasions where a knowledge of Mathematics is required beyond the Mathematics necessary to solve a simple formula, whereas the lack of knowledge of Electricity, Steam and Hydraulics is often a serious handicap to the officer." I will venture to enlarge on this and say that, assuming Latin, Mathematics and Experimental Science were taught equally well, by equally sound methods, and that they proved to be of equal value as forms of mental training (though of course, developing somewhat different faculties), the training gained through Experimental Science would be far the most valuable because the recipients would be brought thereby most intimately into contact with the world and most fitted to help themselves by having their thought-power developed. Of course this is but an opinion, but one which, I venture to think, many share with me; and yet I make no superior claim for the subject, and ask only that it should rank equally with literary and mathematical training among the necessary subjects of education.

It still remains to consider the specific recommendations of the Committee with regard to Experimental Science, as these are most unsatisfactory. Nothing could be more satisfactory than the manner in which the subject is dealt with by the Committee in their general report, paragraph 20, already quoted (p. 592). But on turning to the scheme of the proposed

[1] Dr. Warre was continually harping on this point in his questions to witnesses examined by the Committee. Thus (Q. 3124): "I want to put Geography and History into English, and your composition would be tested in that way. We think, for instance, that Composition is admirably taught by translation from Latin or Greek. (To the witness:) Would you agree with that, that translation from another language is teaching English Composition?"

Again (Q. 3129): "When officers have talked to us of the uselessness of Greek and Latin, they have neglected the fact that Greek and Latin are the great instructors in English." *Witness* (the Rev. A. Robertson): "I quite concur in that."

examination (Appendix A), it appears that not one Experimental Science, but two Experimental Sciences are contemplated, viz. Physics and Chemistry, either of which may be taken in preference to Latin and together with English, Mathematics, and French or German. A most important issue is involved in this recommendation, and it cannot be too strongly opposed.

It is very strange, and a proof of how little we are accustomed to act consistently or to organise, that having found a good thing we rarely make use of it. In the early days of scientific teaching, the elementary parts of chemistry and physics were taught as one subject; but gradually, as the individual sciences developed, this healthy practice fell into abeyance. Then time brought its revenge; it was seen that a very one-sided creature was being trained up; that the subjects were in reality interdependent. Moreover, a revolt had been setting in against the formal stereotyped manner in which chemistry was being taught in the schools; this came to a head about 1887, and a better policy was inaugurated by the Reports and scheme presented to Section B of this Association in 1889 and 1890, which condemned "test-tubing" in favour of problem work and led to the introduction of the quantitative exercises which are now generally admitted to be of the first importance. Although the scheme dealt primarily with chemistry, being the work of the Chemical Section, it yet had a physical basis; physical measurement, in fact, was its life blood, and all the earlier exercises prescribed in it were in essence physical exercises; moreover, the importance of paying some attention to bio-chemical and bio-physical phenomena was not overlooked. As teachers have gained experience of the educational value of the heuristic methods advocated in the British Association scheme, they have been led to apply them more and more widely, and the teaching of Elementary Science has in consequence been regarded with growing favour of late years; more and more has been done to give it the necessary breadth so as to constitute it an effective system of "Nature Study."

The University of London—not the reconstituted body of the present day, but the much-abused examining body of the past—after careful inquiry a few years ago advisably substituted the subject of General Elementary Science for the specific sciences previously prescribed for the Matriculation Examination, and by so doing took a forward step which has generally been admitted by those who can really appreciate the issue to be one of the most important possible from an educational point of view. But the syllabus was imperfectly drawn up—although it had many good points—and the examination was entrusted to men who, besides having little sympathy with the subject, had scant knowledge of school requirements and possibilities. Consequently, the examination was a failure, as everyone foresaw it would be if conducted without proper consideration. The new University has taken the *most unwise* step of reverting to single subjects. It has done far worse than this, however, in making "Science" an alternative subject. Such a reversal of the policy so long pursued by its forerunner can only be described as a *National disaster*. I make this statement with the utmost consideration, and trust that the fact that it is so pronounced from the Chair of this Section may give increased force to my opinion.

It may be claimed that the action taken by the Committee on Military Education is in harmony with that approved of by the Senate of the University of London. The only comfort left open to us is that afforded by the proverb that two wrongs do not make a right. Let us hope that wiser counsels will ere long prevail. The consequences of perseverance in so narrow a policy must be very serious. Consider the effect even from a limited professional point of view. It is widely felt that, owing to the growth of knowledge, it is necessary to specialise if we are to do effective work; but this does not mean that we should be uncultured. We know that the very contrary is the case, and that there was never a time when general knowledge was of greater value than it is at the present day. Yet how little this is recognised. The physicist is already unable to understand the chemist. And although the biologist is attempting to unravel almost transcendental problems in chemistry, he has but the most rudimentary knowledge of the subject. What intellectual pigmies we shall be if we pursue so short-sighted a policy; how ineffective must be our treatment of borderland problems. How little right men of science will have to reproach those who have received only a classical and literary training with lack of general culture if we remain so narrow within our own domain. And from a general point of view the outlook is still more serious. The object of introducing Experimental Science into schools is to give training in knowledge of the world and to cultivate appreciation of its beauties and mysteries. To do this involves resort in some measure to all the sciences. Chemistry and physics are put first merely because they are of fundamental importance, chemical and physical changes being at the root of all natural phenomena.

As to the value of "Science" to military men, it is easy to understand that they should have little conception what it may do for them; having never received proper training hitherto, they cannot have had the opportunity of testing its usefulness or of appreciating its merits. But making all allowances, it is difficult to understand an answer such as that given by Lieutenant-Colonel Murray (Q. 4806) to the Committee on Military Education, viz. that "Science is a narrowing study for the young mind, and we want to widen and open the mind as much as possible; let them learn their science afterwards" (that is, after the entrance examination). The contention of the advocates of "Science" has always been that of all subjects it tends most to widen and open the mind. Why attention should be specially called to this answer by the Committee in their report is a riddle; I hope it was because they desired to shew they could rise superior to the occasion. But the idea that science "can be learnt afterwards" is a very common one, and one of the most pernicious abroad. Learning from books and teachers is a lazy method of learning, and the average scholar is corrupted at an early age by exclusive resort to such methods. Much of the mental inertness of the day is acquired at school by over-indulgence in book study. But apart from this, early youth is the period when the mind is most alert and the desire to acquire and experiment greatest; it is the time when the powers of observing and of reasoning can be most easily developed into fixed habits; in fact, if they are not then developed, it is only in exceptional cases that the omission can be rectified in after life. It is too cruel that Mr. Shenstone, the one witness on the subject heard by the Committee on Military Education, should have given expression to the ill-considered opinion that the beginning of the study of Science necessarily comes somewhat later than that of Latin. The statement shows how prone we are to draw false conclusions, how little we think before we speak. The study of Science begins when the infant opens its eyes; every step it takes when it toddles is an attempt to apply the methods of experimental science; some training in scientific method is given in well-conducted Kindergarten schools; but when school is entered, the curtain is suddenly drawn upon all such rational study; if it be the fate of the child to enter a Preparatory school prior to entering a Public school, he is at once referred back to the times of the Romans and Greeks, his teachers being oblivious to the real lesson to be learnt from the study of the scholastic methods of classical times—that the training given to the youth should be such as to fit him to do his work as a man. How can our officers, how can any of us, be otherwise than ill prepared to do our duty in the world when we are so treated as youths?

Of course all such narrow views, all such narrow actions, as those I have referred to are but consequences of the lack of imaginative power—of our failure to make any scientific use of our imagination. Surely it were time we recognised this, and that we sought to do our duty towards our children. An Arnold who could introduce morality into school method, not merely into school manners, would be a precious gift to the world in these days. Steeped as we are in mediævalism, we need some cataclysm—some outburst of glowing sand and steam such as the world has recently witnessed in the islands of Martinique and St. Vincent—which would sweep away preconceived opinions and give clearness to the atmosphere. American industry is distinguished by the readiness with which manufacturers scrap their machinery and refit. Why cannot we agree to scrap our scholastic and academic ideals, if not our schools and schoolmasters, and refit on scientific lines? If we are to weld our Empire into a coherent whole and maintain it intact, we must do so. Unless we recognise prophets—if progress be allowed to depend on the multitude—we shall perish. And time presses; we cannot with safety much longer remain a "nation of amateurs." An appeal must ere long be made to the masses to enforce the provision of leaders; it must be urged upon

the men that they see to it that their masters are educated; for however democratic we may be in our ideals, history teaches, in a manner which admits of no denial, that leaders are the salt of the earth, and in these days leaders need a deal of training to be effective.

Unfortunately, it too often happens that those placed in authority are the very last to attempt to march with the times. Bodies such as our Universities, the Education Department and the Civil Service Commissioners might have been expected to lead the way, to keep the most watchful eye on all that was happening, and to note and apply all improvements. The very contrary has been the case. As a rule, they have advanced only under severe pressure from outside, and scarcely a change can be credited to their initiative. It does not seem to have occurred to them that an Intelligence Department would be a desirable appendage. All suffer from the fatal blot that discretion and authority are vested only in a few heads of departments; the younger and more active spirits have no opportunity granted them while their minds are plastic, full of courage and instinct with advance; so when the time comes that they can act they have lost the desire through inanition. This is the terrible disease from which all our public offices and many industries suffer. It is right to accord experience its proper value, but it is wrong to put aside youthful energy and inventiveness. Our American cousins owe their advance largely to the recognition of these facts.

At bottom the spirit of commercialism is the cause of much of the contorted action we complain of. Neither Cambridge nor Oxford will take the step which has long been pressed upon them—and never more eloquently than by the Bishop of Hereford in his paper read before this Section last year—to make their entrance examination one which would be in accordance with our knowledge and the recognised needs of the times, and one which would have the effect of leading schools generally to impart the rudiments of a sound general education. They cannot act together and are afraid to act singly, each fearing that it would prejudice its entry if it took a step in advance and in any way sought to influence the Schools. The Colleges vie with each other in securing the best scholars in the hope of scoring in the general competition. And the Schools have discovered that successes gained in examinations are the most effective means of advertising, and are therefore being turned more and more into establishments resembling those engaged in the manufacture of *pâté de foie gras*, in which the most crammable are tutored without the least consideration of the manner in which lifelong mental biliousness is engendered by the treatment. Parents, with strange perversity, worship the success achieved by Tom and Dick, Mary and Jane, and think they are doing their duty by their children in allowing them to be made use of—for private ends. The worst feature of the system is the narrow spirit of trades unionism which it has engendered, which leads to the worship for ever afterwards of those who have gained the prizes, instead of regarding them but as victors for the moment and requiring them at each step to give fresh proof of power. Nothing is more unwise than the way in which we overrate the pretensions of the "first class" man; we too often make a prig of him by so doing. Those who succeed in examinations are too frequently not those most fitted for the work of the world. A long experience has convinced me that the boys a few places down a class are, as a rule, the best material. Those at the top may have acquisitive power, but more often than not they lack individuality and the power of exercising initiative. We must base our judgment in the future on evidence of training and of general conduct, not on isolated examinations. If any sincerity of purpose be left in us, if any sense of the value of true training—of what constitutes true training—can be rescued from the scholastic wreck on which we find ourselves at present embarked, we must institute some form of leaving examination which will give the requisite freedom to the schools and every opportunity for the development of individuality, and at the same time necessitate thoroughness of training and patient regard of every grade of intelligence; leaders will show themselves and will not need to be examined for. Examinations as commercial enterprises must suffer an enforced bankruptcy.

Racing studs must be regarded as luxuries in schools and kept apart from the ordinary stables, these being regarded as the first charge upon the establishment, as the serious work of the world will fall upon their occupants. In other words, special provision must be made for scholars, and they must not be allowed to monopolise attention and set the pace to the detriment of the majority. When Carlyle made the statement that we had in our islands a population of so many millions, mostly fools, he stated what is only a half truth. He failed to realise that the foolishness is very largely begotten of neglect and want of opportunity, not innate. Our schools mostly fail to find out the intelligence latent in the great majority of their pupils, and give it little chance of developing by offering them a varied diet from which to select. During a long experience as a teacher, I have over and over again seen weaklings develop in course of time into strong men when they have been properly encouraged and an opportunity at last found for the exercise of their "talents." The Briton is in this respect a most mysterious creature; you never know when it is safe to call him a fool. All are agreed that the mistakes in the recent war were not due to lack of intelligence, but to lack of training. There can be no doubt of that. All who have taught in our colleges will, I am sure, agree with me that the material sent up from the schools is in substance magnificent, but too often hopelessly unfit to benefit from higher teaching. The things said of those who enter for the military profession are as nothing in comparison with what could be said of those who enter for the professions generally. If our young people fail to show intelligence in later life, it is, as a rule, because the conditions under which we place them in earlier life are such as not only to leave their intelligence undeveloped, but, what is far worse, such as to mar their ability. The best return we can make to those who did such magnificent service in the late war will be to take to heart the real lessons taught by the mistakes, and to see to it that their children and successors generally are trained in a happier school than that in which they were placed.

Examining bodies at the present time do not appear to realise the full measure of their responsibility. To examine well is at all times a difficult task, far more difficult than to teach well. The examiner wields a large measure of authority, and it is imperative that he should exercise this wisely. Examiners should therefore be chosen with extreme care and with due regard to their fitness for the work; but this too rarely happens; the choice falls too frequently on specialists, with little knowledge of educational requirements and possibilities. The examination of boys and girls is far too often put into the hands of those who have no real knowledge of the species and little sympathy with its ways.

There are three courses open to examining bodies—to lead, to maintain themselves just abreast of the times, to stagnate. As a matter of fact, the last is that almost invariably chosen—a syllabus, when once adopted, remaining in force year after year. Consequently, examinations tend to retard rather than to favour the introduction of improved methods of teaching. It is impossible to justify a policy which has such results. The evil effect of examinations would be less if the syllabus were abolished and the limits of examinations very broadly indicated; this is done in some cases, and might be in all. The incompetent examiner and teacher are not in the least helped by the conventional curt syllabus, but the liberty of action of the competent examiner and teacher, and their desire to effect improvements, are materially limited by it. The competent examiner should know what is a fair demand to make of a particular class of students, and should be in a position to take count of the advances that are being made; and the competent teacher should be able to do all in his power to make the teaching effective, and be secure in feeling that his efforts could not fail to be appreciated. To take my own subject, the chemistry syllabus recently laid down for the London Matriculation examination is quite unsuited to its purpose and most hopelessly behind the times. The scheme put forward in the report of the Committee on Military Education is but a bag of dry bones. In the case of several subjects, the South Kensington schemes are full of the gravest faults, their hoary antiquity being their least objectionable feature. Surely a national institution, dispensing public funds, should be the last to hold back the nation; it should be provided with machinery which would enable it to march with the times. In making this criticism I should like to recognise the great work done by Sir William Abney in instituting reforms; but one swallow does not make a summer; a self-acting, governing mechanism is needed which would at all times maintain the balance of practice with progress.

If we consider the process by which decisions on such matters are arrived at, even in the bodies representative of very large interests it is a curiously imperfect one. Usually very few

individuals are concerned. We are all still imbued with primitive instincts. In some way two parties arise, and the question is, which shall conquer? More often than not the true inwardness of the issue presented is left out of account—the considered opinion of the day is scarcely asked for, or if opinions are collected they are not weighted. Therefore calm reason is rarely the arbiter. The conditions of modern civilisation require that some better method shall be devised, which will really enable us to do that which would be of the greatest good to the greatest number. We do not sufficiently remember that while we are tilting, the enemy at our gates is contemplating our failure to maintain and strengthen our fortifications, and quietly advancing his forces to the attack. Speaking of the Navy in the House of Commons not long ago, Mr. Arnold Forster said: "There was a need for some reinforcement of the intellectual equipment which directed, or ought to direct, the enormous forces of our Empire." Surely we may take these words as true generally.

At the present time, when the responsibility of controlling all grades of education is about to be cast upon the community and the actual call to arms is imminent, it is imperative that a sound public policy should be framed and that nothing should be allowed to stand in the way of the public good. It cannot be denied that School Boards have done most admirable service; but there are many who are convinced that in not a few respects they have been disastrous failures and that we need a wider organisation, penetrated with sounder and especially with more practical views. The one essential condition of success is that the public itself treat the matter seriously, realising that their own immediate interests are at stake and that they will be the first to suffer if those who are chosen by them to formulate the new policy and to supervise the work of education are unqualified and, to emphasise my meaning, let me add, unpractical. If the State is to retain any measure of authority, it too must be prepared to exercise that authority wisely. The blame to be put upon School Boards in England for having allowed an unpractical system of education in the schools is as nothing compared with the blame to be put upon the Education Department for having allowed such a system to grow up by the adoption of academic ideals and academic machinery. Until recently, it was a disqualification for an inspector to have teaching experience. A good degree, if not political influence, was the one qualification. Consequently men were chosen whose practical instincts had never been developed, who knew nothing of practical life and of common-place requirements, and nothing of children and their ways; with rare exceptions, the inspectors could look at education only through literary blinkers. To intensify the evil, the wicked system of payment by results was introduced. An inspector such as I have described, working under such a system, could not do otherwise than destroy teaching.[1]

The first necessary step to take will be to reorganise the Education Department, root and branch; to imbue it throughout with sound ideals and lead it to understand its great importance as the head centre of the Educational system; for disestablish as we may, and however much we may favour local self-government, a head centre there must be to correlate the efforts made throughout the country and to distribute wisdom; but its functions will be those of an exchange and inquiry office rather than directive and assertive. At least, such is my reading of the tendency of the *Zeitgeist*. Such a Department will have an Intelligence Board, whose members are partly official, partly unofficial, so that it may maintain itself in constant touch with outside opinion and effort. One function of this Board will be to preside at a monthly bonfire of red tape and official forms; for in future, even if no other subject of Government concern be kept in a lively and living state, education must infallibly be. The whole staff of the office, including the inspectorate, will be required to avail itself of that most valuable institution, the sabbatical year, *i.e.* to spend every seventh year in some other employment, so that they may not forget that the world has ways sometimes different from those pictured within the office and which it is advisable to take note of in education. Refreshed and invigorated, they will return to work, prepared to sacrifice all sorts of traditions and to recognise the existence of short cuts across fields which had before appeared to be of interminable dimensions; and as it will be required that they spend a certain proportion of their close time in the company of children—if they have none of their own—they will learn that a child has ways and views of its own, none the less interesting and worthy of consideration because they are somewhat different from those of grown-up people.

[1] The inspector destroys teaching, because he is bound by law and necessity to examine according to a given pattern; and the perfection of teaching is that it does not work by a given pattern (Thring).

It is fortunate that the Technical Education Movement has been coincident in England with the development of the School Board system. Those engaged in it have worked untrammelled by official requirements, and much original thought has been enlisted in its service. In essence it has always been a revolt against the academic ideals permeating University education and the schools generally; the faults of the schools, in fact, are the more obvious in the light of experience gained in technical education, which will now come to our aid in correcting them.

The really serious tasks before those who direct the work of education in the immediate future will be the choice of a programme and the provision of capable teachers. If they enter on these tasks with a light heart, God help our nation; they will thereby give proof that they have no true conception of the great responsibility attaching to the position they occupy. Let no man offer himself for the work unless he feels certain that he is in some degree qualified.

As to the programme, it may be said that that is for the teachers to settle; and so it should be. But it cannot be denied that, by long-continued neglect to read the writing on the wall, they have lost the claim to legislate; they have shown that they do not know how to legislate. The public must lay down the programme in its broad outlines; teachers must fill in the details. The task imposed upon the schools will be to develop the faculties generally—not in the lop-sided manner customary heretofore—and especially to develop thought-power in all its forms and the due application of thought-power.

I believe that gradually a complete revolution must take place in school procedure, and that the school building of the future will be altogether different from the conventional building of to-day, which is but an expansion of the monkish cell and the cloister. Instead of being a place fitted only for the rearing of what I have elsewhere termed desk-ridden emasculates, the school will be for the most part modelled on the workshop, giving to this term the most varied meaning possible, and a great part of the time will be spent at the work bench, tool in hand. Nature's workshop will, of course, be constantly utilised, and the necessary provision will be made for outdoor exercise and physical training. Scientific method will underlie the whole of education.

It will be recognised that education has two sides, a literary and a practical; that the mind can work through fingers; in fact, through all the senses; that it is not embodied only in the so-called intellect, a narrow creation of the schools. The practical training will therefore be regarded as at least equal in importance to the literary. Heads of schools will not only be potential bishops, but almost all careers will be open to them. In fact, I trust the system will be in operation which I have already advocated should be applied to the Education Department, and that the members of the school staff will be forced out into the world at stated intervals, so that they may not degenerate into pedants capable only of applying set rules much after the manner of that delightful creation Beckmesser in Wagner's opera "Die Meistersinger."

The class system will be largely abandoned. Children's school time will not be chopped up into regulated periods in a manner which finds no analogy in the work-a-day world, but they will have certain tasks confided to them to do and will be allowed considerable latitude in carrying them to completion. In fact, they will be treated as rational beings, and their individuality and self-respect developed from the outset. The Boer War will have taught us to adopt open-order teaching as well as open-order firing. Schools will glory in turning out individuals, not machines. The success of the Americans is largely due to the way in which Republican doctrines are applied to the up-bringing of children in America. We must follow their example, and set our children free and encourage them to be free at an early age. The human animal develops at a sufficiently slow rate in all conscience, and there is little need for man to retard his own development. School, with its checks upon freedom and individuality, should be quitted at seventeen at latest, I believe, and all subsequent systematic training should take place at college. Boys are kept at school after seventeen mainly for the purposes of the school. It is claimed that by

remaining they gain most valuable experience by acting as monitors and prefects; but this experience is enjoyed only by the few, and might be obtained at an earlier age. Then it is said that seventeen is too early an age to enter Oxford or Cambridge, but this has only been the case since schools have retained boys to prepare them for examinations and in order that they might assist in the management. I believe that the attempts which have been made in these latter days to do college work at schools and to establish engineering sides in order to find work for senior boys have had a most detrimental effect. It is said that the training given in technical schools is too far removed from practice; but how much more must this be true of technical work done under school conditions? The excessive devotion to literary methods favoured by schools and the older Universities tends to develop unpractical habits which unfit many to face the rough-and-tumble life of the world, and is productive of a disinclination for practical avocations. By leaving school at a properly early period this danger is somewhat lessened; moreover, it is necessary in many walks of life that school should be left early in order that the school of practice may be entered sufficiently soon to secure the indispensable manual dexterity and habits. For a long time past we have been drifting away from the practical, and those who are acquainted with the work of the schools, especially the elementary schools, are aghast at the influence they are exercising in hindering the development of practical ability. We must in some way counteract this tendency. On the other hand, we have to meet the views of those who very properly urge that it is cruel to withdraw children from school even at the age we do. The two views must in some way be reconciled. The only way will be to so improve the teaching in schools that school becomes a palace of delight and the continuation school a necessity. The habits formed at school should be such that study would never be intermitted on leaving school. At present school so nauseates the majority that on quitting it they have neither desire nor aptitude to study left in them; the work done in it is so impossible to translate into ordinary practice, so foreign to outside requirements.

The problem can only be solved by the scientific use of the imagination. The solution I would venture to offer is that an honest attempt be made to teach, not only the three R's, but also a fourth, Reasoning—the use of thought-power—and that a properly wide meaning be given to all the R's.

Of all powers that can be acquired at school, that of reading is of first importance. Let teachers read what Carlyle says in the "Hero as Man of Letters," correcting his exaggerations by reading into his words some of the lessons taught by experimental science. Reading is not taught in schools in these days; if it were, people would not waste their time on the rubbish which now figures as literature and for which a rational substitute *must be found*. A well-read man is worshipped at the Universities and is held up to all comers as a pattern. Why should not children be encouraged to be "well read"? Let us admit this and sow books in their path. Thring, in giving utterance to his "Practical Thoughts on Education after Thirty Years' Work," speaks strongly on this point. "Great interest will make up for want of time. Create great interest," he says; and these are noteworthy words. "As soon as children can read, throw away all lesson books for a time. Let them read—let them read aloud—really read, not tumble through the pages. Give them to read poetry, the lives of good men, narratives of noble deeds, historical stories and historical novels, books of travel, and all the fascinating literature of discovery and adventure. The person who has once learnt to read well is tempted to go on. And such books, selected by a carefully graduated scheme, would supply endless knowledge whilst kindling the mind, without any waste of time from drudgery and disgust. Geography, history and power of speech are all comprised in such books if properly used."

Thring here advocates what I would advocate—the *incidental* method of teaching. Why should there be any set lesson in subjects such as history and geography? Nothing is worse, more stereotyped, more cramping to the intellect than the set lesson of so many lines or pages, of a sort of Liebig's Essence of information, with the attendant obligation of committing the facts recorded in them to memory. The child, like the restive, high-mettled young steed, wants to be off and away—not to be held severely in hand. Why should not the method by which we get up a subject in later life be followed in schools? At least it should be properly tried. Let us give freedom to children, and at least during early years lead them to read hard and wisely; they will do so gladly; and give them pictures innumerable in illustration of their reading. And children must not only be taught to read books; they must learn also to regard and use them as sources of information; the habit of flying for information to books must be cultivated. They must be constantly referred to dictionaries and works of reference generally; they must be set to hunt up all sorts of stories. Of course the scholastic Beckmesser will object that such a system is impossible, that there would be an end to all discipline; but to say this is to show a want of understanding of children and of faith in them, and is proof of failure to recognise their power of accepting responsibility when it is properly put upon them. The secret of success lies in beginning sufficiently early; once let them appreciate what they are doing and the majority will work eagerly and spontaneously.

But when the full meaning is given to the first of the R's, it will be held to cover, not only the reading of printed or written character, but also the reading of some of Nature's signs, to the end that sermons *may be* discovered in stones and good in everything. That is to say, at the same time that they are acquiring the true art of reading, they must be learning the true art of experimenting—to find out things by putting questions of their own and obtaining direct answers. The teaching of the elements of experimental science must therefore accompany the teaching of reading. And great care must be exercised that the palate for experimenting, for results, is not spoilt by reading. The use of text-books must be most carefully avoided at this stage in order that that which should be elicited by experiment is not previously known and merely demonstrated—a most inferior method from any true educational point of view, and of little value as a means of developing thought-power. I regard Huxley's "Physiography," for example, as a type of the book to be avoided until method has been fully mastered. The great difficulty in the way of teaching the art of reading arises from the comparative paucity of readable books for young people. Text-books are not readable, and in fact tend to spoil reading; and the majority of books are written for grown-up people having considerable experience of the world. The mistake is too commonly made of expecting children to master "classics." On the other hand, we need not fear allowing advanced books to fall into the hands of children; they are the first to despise the namby pamby stuff that is too frequently offered to them. A new literature must be created, if education is to be put on a sound basis; something beyond mere word-painting is required. Books are wanted, written in a bright, attractive and simple style, full of accurate information, which would carry us over the world and give clear pictures of all that is to be seen, as well as of the character and customs of its inhabitants; and books are wanted which, in like manner, would carry us back in time and sketch the history of the peoples of the earth. The various branches of science all need their popular exponents; our books are for the most part too technical, and whilst much has been done to advocate the introduction of "Science" into general education, little has been done to make this possible. Unfortunately, those who attempt to write readable books are too frequently not those who are possessed of sound knowledge, and it is time that it were realised by those who could write well and accurately that there is a duty incumbent upon them; on the other hand, something should be done to stem the torrent of text-books which is now flooding the field of education with the destroying force of a deluge and making proper reading impossible.

The true use of books has yet to be found and admitted; we do not sufficiently recognise their value as stores of information and savers of brain waste. Why should long trains of facts be committed to memory but to be forgotten? It is impossible to believe that such a process is mental training; it must involve loss of energy and mental degradation. In future we must give the training at less cost and teach the art of going to books for minute details whenever they are wanted. Nearly every subject is taught in an eminently selfish manner at the present time, the expert declaring that the learner must become acquainted with all the main facts of the subject, instead of recognising that it is far more important to acquire knowledge of first principles together with the power of acquiring the knowledge of facts whenever these become necessary.

The second R may be held to cover, not only mere writing, but also composition. Why is the art of composition taught so badly? Because it is impossible even for children to make

bricks without straw; they have little to write about under ordinary school conditions. The subject is also one, I believe, which must be taught incidentally, at least during the earlier years, and chiefly in connection with the experimental work; in fact, to make this last the training it should be an absolute record of all that is done, must be properly written out, and while the work is being done too. Many teachers, I know, shy at this, and say that it is their business to teach "Science," and not literary style; but they are wrong, and must inevitably accept the burden if they are to succeed in teaching "Science" at all. An experiment, like an act, "hath three branches"—to conceive, to do, to utilise; a clearly defined motive must underlie it; it must be properly executed; the result must be interpreted and applied. It is only when the motive is clearly written out that it is clearly understood—that the meaning or intention of the experiment is clearly grasped; and this is equally true of the result. Of course, it is necessary to proceed slowly and not to demand too much from beginners; but it is surprising how the power grows. Drawing, of course, must be included under the second R; but this also may with advantage be taught incidentally, and only receive individual attention at a later stage, when those who show aptitude in the incidental work have been selected out for higher instruction.

The third R must be held to cover, not merely the simple rules of arithmetic and all that is necessary of formal mathematics, but also measurement work. Mathematics claims to be an exact subject, and therefore must be treated exactly and made the means of inculcating training in exactness, and not on paper merely, but in fact. Moreover, physical science reposes on a basis of exact measurement, so that the introduction of experimental work into schools involves the introduction of measurement work as a matter of course.

The fourth R—Reasoning—will necessarily be taught in connection with every subject of instruction, not specifically. It is introduced as marking the absolute need of developing thought-power: and, in point of fact, should be put before all others in importance.

Under such a system as I suggest, the time of study would be spent in two ways—in reading and experimenting. But whatever we do, let us be thorough; the danger lies in attempting too much, too many things. Each step must be taken slowly and warily, and a secure position established before going further.

Ireland is fortunate at the present time in that far-reaching changes are being introduced into its educational system. A body of men are engaged in this work who are, I believe, in every way specially qualified to promote reforms and earnestly desirous of developing a sound policy. The Irish race have rich powers of imagination such as no other section of the nation possesses, and it is only necessary that these powers be trained to considered and balanced action to make the Irish capable of deeds before which the splendid achievements of the past will appear as nothing. Of course, the development of a true policy must come about slowly, and we must not be too impatient of results, but give every encouragement and all possible support to those engaged in the work. It is before all things necessary to remember that the school is a preparation for life, not for the inspector's visit; in the future, the inspector will act more as adviser and friend, let us hope, than as mentor.

Turning to my own subject, the programmes laid down for primary and intermediate schools appear to me to be well thought out and full of promise, the only fault that I might be inclined to find being that perhaps they are somewhat too ambitious. But very able men are directing the work, and they should be able to see that thoroughness is aimed at before all things. Nothing could be more gratifying than Mr. Heller's statement in the Report for 1900, "that the Irish teachers as a whole seem to possess a great natural taste and aptitude for science and the method of experimental inquiry." May they seek to set the example which is sorely needed to teachers in other parts of the kingdom. I fear there has been a good deal of hand-to-mouth teaching in the past; to avoid this, the teacher should not only have a carefully drawn-up scheme of work, but should keep a diary in which the work accomplished each week is carefully recorded. In this way the weaker teachers will check any tendency they may have to relax their efforts, and inspectors will be in the position to understand at once what progress is being made. Education, unfortunately, is subject to booms as the money market is; just now the "Nature-study" boom is on. We must be very careful not to let this carry us away; whatever is done must be by way of real Nature-study, and must have very simple beginnings. In most of the work that is being boomed, the presence of the eternal book is only too evident, and such teaching must be worthless. Let the teachers remember that the great object in view is to acquire the art of experimenting and observing with a clearly defined and logical purpose. If they once learn to experiment properly, all else will follow. The inspectors must give constructive help to the work; they too must be students and labourers in the cause of progress, not mere commentators. And there will be a great opportunity for experts to assist who can be helpful to schools. Every school should be provided with a workshop, simply equipped with flat-topped tables, in which all the subjects which are taught practically can be taken. Elaborately fitted laboratories are not only unnecessary, but undesirable; the work should be done under conditions such as obtain in ordinary life. A due proportion of the school time must be devoted to experimental studies; no difficulty will arise when it is seen that so much else is taught incidentally; and that this is the case must be carefully borne in mind in arranging the curriculum—otherwise there will be much overlapping and waste of time. Lastly, every effort must be made to keep down the size of the classes. I trust that in Ireland the girls will receive as much attention as the boys. Experimental teaching is of even greater value to them than to boys, as boys have more opportunities of doing work which is akin to it in the world. The work done by girls should of course bear directly on their domestic occupations.

If we are to improve our schools, the teachers must be trained to teach properly—or rather, let me say, must be put in the right way to teach, because practice and experience alone can give proficiency. This is the most difficult of all the problems to be faced in providing for the future. It is the one of all others to be thought out with the greatest care, and in solving it the help of all who can help must be secured. No amount of didactic teaching will make teachers; the training must be practical. To graft on the ordinary training a course of lectures on the theory and practice of teaching plus a certain amount of practice in a school is not enough. How can we attempt to teach the theory and practice of teaching when we are agreed that we do not know how to teach most subjects? How can a master of method instruct us how to teach subjects of which he has only heard? It cannot be done; in point of fact, we are talking about the thing—beating about the bush—instead of treating the problem as one which can only be solved by experiment. To teach method, you must know your subject; one man cannot know many subjects. Of course there are quite a number of good general rules to be learnt, but the application of these must rest with the specialist; and the only proper way of giving training in method is to teach the subject in the way it seems desirable that it should be taught. The end result of training should be the development of a spirit of absolute humility—of the feeling that no task is so difficult as that of teaching properly, no career in which finality is more impossible to attain to, no career which offers greater opportunity for perpetual self-improvement. The effect of the narrow and unimaginative system in vogue to-day is to send forth a set of young persons who arrogantly consider that they are "trained"; if they would only think of the amount of preparation involved in training for athletic competitions, or in training race-horses even, they would entertain more modest views and be aware that they have everything to learn when they commence their work. The Beckmessers reign supreme in our training colleges of to-day; they must be got rid of, and true modest experts introduced in their place. The test of efficiency must be a real one, not that of a mere final examination. The inspectors must see to it that the instruction is given always with a view to the fact that the students are to become teachers, which at present seems to be the last consideration borne in mind. Every effort must be made to secure a higher class of student for the training colleges; a fair secondary training *must be insisted on.* A narrow spirit of trade unionism pervades the primary school system at the present time, and School Boards and managers of Pupil Teachers' Centres make no effort to secure the assistance of secondary teachers.

My receipt for a training college would be: Develop thought-power and individuality; develop imagination. Teach whatever will do this most effectively, and let special subjects be studied in the way that may best be followed in teaching them subsequently.

It is to the lasting shame of our State organisation and of our School Boards that so little has been done to provide competent teachers.

The future rests with the Universities; but to save the nation the Universities must be practical, and broader conceptions must prevail in them. A course of training which will give true culture must be insisted on. The Universities have recently shown a disposition—to use a vulgarism—to throw themselves at the heads of the military authorities and to make special provision for the training of military students. It is much more their office to train teachers. Why should not the example to hand in the engineering school at Cambridge be followed? Why should not a special Tripos be established for teachers in training? I believe this to be the true solution of the problem.

The desire now manifest in several of our large towns to establish new Universities comes most opportunely, and should receive every possible encouragement from all who have the interests of our country at heart. I believe the objections to be altogether fanciful and the outcome of academic views. It is said that the value of the degree will go down like that of Consols. But in what does the value of a degree consist? Simply and solely in the evidence it affords of training. We regard the Oxford and Cambridge degrees as of value because they are proof that their possessors have lived for some time under certain conditions which are recognised to be productive of good. The degrees of other Universities must soon come to be regarded as proof of sound and healthy training. It must become impossible to obtain degrees such as the University of London has been in the habit of awarding, which have been the result of mere garret-study; proof of training will be required of all candidates for degrees.

But I must now bring this Address to a conclusion. The only apology that I can offer for its length is that having had over thirty years' experience as a teacher, and being profoundly impressed by the serious character of the outlook, the opportunity being given me, I felt that, as the walrus said to the carpenter,

> "The time has come, . . .
> To talk of many things:
> Of shoes, and ships, and sealing-wax,
> Of cabbages, and kings,
> And why the sea is boiling hot,
> And whether pigs have wings"
> ("Alice through the Looking-glass.")

This list of subjects is no more varied and disconnected—the problems set no deeper—than those to which we must give our attention in dealing with education; and the sooner the fate of the oysters is that of our present educational "system" the better. Having shown by this quotation that I am not an absolute modern, but have some knowledge of the classics, let me finally say, in the words of another poet—of him who on various occasions gave utterance to much wisdom at the breakfast table, that "I don't want you to believe anything I say, I only want you to try to see what makes me believe it."

Something more than an apology for an Education Act such as the powers are now engaged in shaping for us must be framed at no distant date, and a determinate policy arrived at. That policy may perhaps be found in the words put into Hamlet's mouth:—

Hamlet. To what base uses we may return, Horatio! Why may not imagination trace the noble dust of Alexander, till he find it stopping a bung-hole?

Horatio. 'Twere to consider too curiously, to consider so.

Hamlet. No, faith, not a jot; but to follow him thither with modesty enough, and likelihood to lead it, as thus: Alexander died, Alexander was buried, Alexander returneth into dust; the dust is earth; of earth we make loam; and why of that loam, whereto he was converted, might they not stop a beer barrel?

> Imperious Cæsar, dead and turned to clay,
> Might stop a hole to keep the wind away;
> O, that that earth, which kept the world in awe,
> Should patch a wall to expel the winter's flaw!

Shakespeare thus taught the use of the imagination before Tyndall! The fact that we can now carry our imagination far further afield and contemplate the survival of atoms once embodied in imperious Cæsar in the flowers and fruit which deck the fair face of Nature—a higher end than that Hamlet paints—may serve to justify the adoption of a method he advocated. Modern progress is based on research—the application of imagination. Surely then there is every reason to make the spirit of research the dominant force in education!

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. C. F. MYERS WARD, of the University College, Sheffield, has been appointed lecturer in physiology at the Charing Cross Hospital Medical School, vice Mr. Benjamin Moore, who was recently elected to the newly established chair of Biological Chemistry at the University College, Liverpool.

THE jubilee of Sydney University was celebrated on October 1, when addresses of congratulation were presented from British, colonial and foreign universities. The Australian universities were represented in an address by Prof. Tucker, and Prof. Baldwin Spencer, F.R.S., spoke for the English universities.

REFERRING to the Education Bill, in a letter in Monday's *Times*, Sir Henry Roscoe favours the view first stated in NATURE, namely, that the part of the Bill dealing with secondary education should be dealt with separately and passed before taking that concerned with primary instruction. Since this suggestion was made in these columns, excitement over the religious difficulty involved in the representation clause of the Bill has greatly increased, and there seems little hope that a compromise will be effected between the contending clerics. It is now clear that the Government would have been well advised to have divided the Bill into two and settled secondary education apart from primary education. As Sir Henry Roscoe remarks, "To the mind of the nation at large, the question as to whether children are to be taught the Catechism or not looms small in comparison with that as to whether the next generation can be better prepared than our own to sustain and improve the industrial and commercial position of the Empire." Whatever may be thought about religious instruction in primary schools, it is unreasonable to delay the coordination of secondary education until the various parties have settled their differences, more particularly as public opinion is in favour of placing secondary education on a sound basis as soon as possible.

CONTENTS.

THURSDAY, OCTOBER 16, 1902.

THE END OF THE WORLD.

Der Untergang der Erde und die kosmischen Katastrophen. Von Dr. M. W. Meyer. Pp. viii + 38·) (Berlin: Allgemeiner Verein für deutsche Litteratur, 1902.)

AT various times and by authorities of very varied reputation, but at tolerably frequent intervals, we are invited to consider the problems that are connected with the origin or the decay of the cosmos. It is doubtful in which category the present volume should be placed; the author, indeed, writes decay on his cover, but his pages have more to do with formation and development. The main thought running through the book is to declare the existence of a cycle of events, which may be accompanied with catastrophes of greater or less severity, but tending always to recovery and restoration. This is no new thought, and until some epoch-making discovery such as that of the spectroscope or the principle of the conservation of force widens and directs the issues of scientific investigation, it is difficult to understand how anything new can be written on the cosmogony as a whole. Dr. Meyer presumably thinks differently, and, with the pen of a ready writer, he is willing to rearrange, in a very pleasant manner, the few facts that have been collected, and to repeat the views of the original thinkers and workers on this fascinating subject. Occasionally, Dr. Meyer wanders slightly from recognised lines, and is then, as we think, neither so accurate nor so interesting as when he keeps on the well-trodden paths that his predecessors have followed. If, however, this rearrangement had been nicely managed, we could have forgiven the author much. If he had unfolded before us a panoramic view, in which the development of the cosmos could be traced continuously and uniformly, or had pictured for us the gradual cessation of the phenomena with which we are familiar, we could have welcomed his book as a contribution to popular scientific literature. But in this respect we do not think Dr. Meyer has done himself justice. The successive chapters of his book have too much resemblance to articles in a popular magazine, and may possibly have done duty in that capacity. Each chapter may read pleasantly enough, but the author has not nicely welded his material and dovetailed his story together. As evidence of the traces of magazine writing, we may quote the following passage (p. 201):—

"... brennt nicht die Wohnstätten der Männer nieder, die für die Freiheit ihres Landes kämpfen, das sie mit schwieliger Hand der Wildnis abgetrotzt haben, drängt anderen nicht euer Christentum auf, bevor ihr es nicht übt an euren eigenen Brüdern...."

Such interpolations have very little to do with the outburst of the new star in Perseus, in the description of which this occurs, but the passage is reminiscent of a style which we will hope has passed. It certainly would have been in better taste to have omitted it from a scientific treatise.

It is a little uncertain how far we may regard this book as the reflection of German thought and the expression of views currently held in astronomical circles in that country. Dr. Meyer has, however, filled positions of some scientific importance, and may to that extent be regarded as an authority. It should therefore have some interest to compare in detail the views he holds on the construction of the universe with those that obtain in this country, more especially on points which we are inclined to regard as having passed beyond controversy and to be generally accepted. Obviously, however, only a few such points can be selected, and the history of the moon is the most conspicuous instance, because it has been made the subject of an elaborate inquiry, in which it has been shown that the obliquity of the ecliptic, the eccentricity and inclination of the lunar orbit, the period of revolution of the moon and the rotation of the earth are coordinated together on the hypothesis that the moon originally existed near the present surface of the earth, and with small differential motion with respect to it. Further, that the discussion of the moment of momentum amongst the several planetary systems shows that the condition, obtaining on the terrestrial, differs widely from that of other planets, pointing to the necessity of unique treatment. But the references to Prof. G. H. Darwin's work are so scanty that we should doubt if Dr. Meyer has read it, or whether any popular account of the investigation exists in Germany.

To explain the origin of the planets and satellites, the author starts with a collision, and finds the materials for the construction of a new universe in the débris of previously existing, but now shattered, suns. This material will consist of gas, molten particles of every conceivable size, and solid fragments. These particles, in the form of dust, meteors, even gleaming suns, are originally gifted with rectilinear motion, but by a process the author does not fully explain, this motion is converted into spiral movement and finally becomes elliptic, characterised by considerable eccentricity, which diminishes with time until an approximately circular form is reached. At least, this process is followed by the more solid portions which are destined to become suns and planets; some portions have their velocities increased by collision, and are carried away to form wandering suns. The actual formation of a sun or planet by the process of conglomeration—a feature common to all cosmogonies—is very difficult of explanation, and the author can follow what train of reasoning he pleases without much fear of hostile criticism, though the necessity of passing through the stage of a double nebula is not very apparent.

With his centres of condensation and space charged with dust and meteors, Dr. Meyer apparently follows the suggestions of the late M. Faye, and assumes that many meteors moving in eccentric orbits strike against the nucleus and are absorbed by it, maintaining an elevated temperature in the central body by impact. Our moon and the satellites of other planets seem to have come into being simultaneously with the primaries, being formed from secondary rings, the separate existence and stability of which are not explained. But as condensation proceeds on the secondary rings, the bodies so formed necessarily cool more quickly than the larger planetary masses, and the precipitated meteoric matter, which is absorbed by the glowing and fluid planets without any difficulty, leaves holes in the thin crust of the satellite,

which is not yet sufficiently rigid to resist. The result is that phenomena resembling lunar craters are produced. These craters, therefore, are not the result of ejections resembling volcanic eruptions from within, but are the results of action from without. Further than this, the matter carried into the body of the moon will in its turn be melted in the heated interior; consequently the thin crust will no longer be able to support the internal pressure, and rents or fissures of the hardened exterior will take place, and this is the cause of the bright streaks or radiations which can readily be seen on the most superficial examination of the moon. It might be urged in opposition to this view that the molten matter ejected from the interior must soon cool, and not only destroy the traces of the meteoric bombardment, but would also thicken the crust and tend to prevent the penetration of fresh meteors. If one asks why the earth or Mars does not show similar signs of precipitated matter, Dr. Meyer is ready with his answer. By the time that the greater mass of a planet had sufficiently cooled, all the larger débris, the results of the original collision, had been absorbed, and the smaller masses either fell upon the stiffening crust without penetrating it, or were volatilised by friction with the atmosphere, which in those days, it is suggested, was more dense than at present. And if anyone, still unconvinced, asks how it is that Jupiter, for example, can drink up all the matter in a cosmical ring extending into indefinite space, and yet refuses to swallow the small mouthful which in the form of the fifth satellite tantalisingly tempts its capacious appetite, the answer is, wait. All the satellites will eventually be drawn in and form an integral portion of their respective primaries, just as these in their turn will be absorbed in the sun, to be followed again at immense intervals of time by the crashing together of defunct suns producing a larger set of planets with a larger and hotter sun, a solar system on a vaster scale than that in which we play our little part. And so growing in grandeur but diminishing in number, the final catastrophe will come, when there are no more suns to produce collisions, and one huge body cooled to the zero of space, void of available energy, will mark the final outcome of cosmical motion.

This, if we understand our author, is the final state of rest, but there are qualifications introduced which may modify this conclusion. We have endeavoured to draw the conclusion without entering into the limitations which depend, more or less, "in unsern unvollendeten Geist." The only objection one might urge is to the insistence on the lowering of the temperature of the mass to that of the absolute zero. It is only necessary for a uniform temperature, however great, to exist throughout the whole, when a practically useless state of kinetic energy would result, and no work would be possible.

On this world, however formed, it is necessary to introduce life, and, if possible, without a definite creative act implying a breach of continuity. Dr. Meyer follows, but without acknowledgment so far as we have seen, the hypothesis of Helmholtz or of Kelvin. We imagine that the author regards life as old as matter itself, and that its transition from a defunct world to a new one is effected by means of germs, borne through space on fragments; or so-called meteors, and whenever such germs meet with a favourable environment the processes of life are continued. In a collision, heat would be generated only in proportion as motion is destroyed, so that, as the author is careful to point out, fragments could escape without any great development of heat or necessary destruction of all forms of life. But we do not understand so clearly his theory of the method by which the meteoric fragment, carrying life to a new world, finds itself deposited there. But this is of little consequence, since meteors do come here, and if their surface is heated by friction, the interior can be of lower temperature. Or it can very well happen that germs lying on the surface would be blown away in the highest and most attenuated strata of the earth's atmosphere before the fragment reached the denser parts of the gaseous mass, where the compression becomes great enough to generate considerable heat. The author, however, seems to think it necessary to give to the meteor the same velocity as that of the earth, so that it is quietly and gently deposited on the surface without any arrest of motion and therefore without any increase of temperature. Indeed, he seems to think that meteors, bringing with them enormous masses of water, can accompany the earth for some days in its journey round the sun, giving rise to severe local storms, and marvels that meteorologists have not entertained such explanations as legitimate and worthy of consideration. It is true that the author does not say that these meteors are moving in a circular orbit, but he allows this to be inferred, since parabolic velocities do not seem to be considered. We gather from an account that the author gives of a controversy with Dr. Palisa that that astronomer has had some difficulty in following Dr. Meyer's views, and, so far as we can follow the account from the description of one of the disputants, we would respectfully associate ourselves with the opinion of Dr. Palisa.

We have dwelt, perhaps, at too great length on the points of difference that separate us from the author, and have no space to enter on other matters, which we would do the more willingly since no note of disapprobation need accompany our remarks. In many respects, the book is very interesting, and many chapters can be read with equal pleasure and profit, though the connection with terrestrial catastrophes is not very apparent. Dr. Meyer has selected a subject of great interest, but one on which diverse views can be maintained more or less legitimately. He can write pleasantly and clearly, and while his book may be instructive to the general reader, for he studiously avoids all technical expressions, it should not be offensive to the most orthodox theologian.

ARTIFICIAL MINERAL WATERS.

The Evolution of Artificial Mineral Waters. By William Kirkby, F.L.S. Pp. x + 155. (Manchester: Jewsbury and Brown, 1902.) Price 3*s.* 6*d.*

THIS little book has been written with the object of showing the origin and development of the mineral water industry, an industry the commercial importance of which may be to some extent gauged by the author's statement that our annual exports amount to more than

one million dozens and that, directly or indirectly, it gives employment to no less than 25,000 persons in London alone.

In his historical sketch of the evolution of artificial mineral waters as we know them to-day, the author shows that progress has been made along two main lines. The existence of these popular beverages undoubtedly had its origin in the desire of the earlier physicians to prepare by artificial means saline solutions which should have the same therapeutic and curative effects as the waters obtained from well-known natural springs such as those of Epsom, Seidlitz or Bath. This necessarily involved some knowledge of the chemical nature of their constituents, and it was not, therefore, until Boyle had given birth to analytical chemistry, and Bergman had brought his genius and industry to bear upon the chemical examination of the waters from many of the mineral springs, that such imitation became possible. At the same time, much speculation was being indulged in as to the exact nature of that wonderful "principle" which gave to many of the natural waters their sparkling character and piquant flavour; and the numerous researches which were being made in this direction culminated in the great discovery by Black of the chemical identity and true nature of carbonic acid gas. Along both these lines the author traces the gradual development of the mineral water industry, showing in true perspective and with due attention to their relative importance the various discoveries or steps by which its present position has been reached. In this connection, we think that the author has attached rather too much importance to Brownrigg's share in the discovery of the true nature of carbonic acid gas, and has perhaps given too little prominence to the masterly researches and brilliant deductions of Black. In the main, however, the chapters dealing with the work of the earlier discoverers are accurately and clearly written, and the book should certainly be read by all who are desirous of acquiring an intelligent knowledge of the beginnings and development of this now important industry.

There are, unfortunately, a few blemishes which ought scarcely to have escaped the author's notice. Thus we are told on p. 3 that the latter half of the eighteenth century witnessed the birth of chemistry, while on p. 13 that honour is assigned to the seventeenth. Whether we are to consider the former, the latter, or, indeed, either of these statements correct will naturally depend upon the precise meaning we are to give to the word "birth," but we presume that the author had in his mind the eighteenth century, which witnessed the labours of Black, Cavendish, Priestley, Scheele and Lavoisier, to mention only some of the giants who laid the foundation on which the wonderful superstructure of modern chemistry has been reared.

The statement on p. 34 that "it is possible to-day to obtain by mechanical and other means water of as great chemical and bacterial purity as any natural water from the deep springs" presumably refers to filtration, but is not by any means clear. On p. 67 we are told that Macquer purified carbonic acid by passing it through a vessel "containing lime and water," but are not told how much of the gas passed through. In connection with the use of sodium bicarbonate for the preparation of carbonic acid gas, the author makes, on p. 120, the truly astonishing statement that precautions have to be taken to prevent any *ammonia* present as an impurity *from passing over with the gas into the gas holders*. We should have thought, as a matter of fact, that the presence of the acid used for its decomposition would have constituted a sufficient "precaution." In one or two places, the language is a little involved, and there are several misprints and slips, such as Becheri for Becher on p. 42, Thiloria for Thilorier on p. 60, and *unabsorbed* would have been better than *unattached* on p. 120. The chapter on the syphon and its development is well written, and like the rest of the book is clearly illustrated by means of well-executed drawings. The author states in his prefatory remarks that he does not intend this to be a manufacturer's handbook, and that therefore he has given no formulæ for the preparation of the various waters. For the same reason, presumably, the description of manufacturing processes and machinery is contained within the limits necessary to render the book acceptable to the general reader. It contains a good index and a well-compiled bibliographical table, and we can, in conclusion, heartily commend it "to all whom it may concern." We cannot, however, help feeling that the author would have done well to have given his book a more independent character by dwelling with rather less emphasis on the excellence of the plant and manufactured products of a particular firm. A. C. C.

DEVELOPMENT OF THE HUMAN EMBRYO

Human Embryology and Morphology. By Dr. A. Keith. Pp. viii+324. (London: Edward Arnold, 1902.) Price 12*s*. 6*d*. net.

DR. KEITH is an accomplished anatomist, and in this morphological study of the development of the human embryo he has given us a valuable account, the result of wide and exact personal observation, of all the later phases of organogeny.

The descriptions of the changes that occur during the formation of the face and neck, the alimentary tract, the central nervous system, the heart and blood-vessels, the history of the development of the skeleton and musculature of the head and trunk, are evidently the work of one who is thoroughly familiar with the anatomy, not merely of the human subject, but of the apes and other mammals as well; and in what we may term the "anatomical embryology" here set before us there is much which will be of permanent scientific worth, apart from what is of practical importance for the ordinary surgeon.

From the other aspects, however, we regret that this treatise is less satisfactory. The earnest student who expects to find here a critical exposition of the thorny problems of modern embryology, or even a sufficiently accurate statement of the facts, will be sadly disappointed.

The account of the formation of the germinal layers and of the early changes in the mammalian blastocyst is not only inadequate, it is erroneous; we are told, for instance (p. 89), that "in lower vertebrates the mesoblast is entirely produced from the hypoblast," and (p. 243)

that it is "highly probable that the cœlom was originally a series of segmental diverticula derived from inflections of the hypoblast," while no attempt at all is made to discuss the difficult question of the significance of germinal layers. The chapter on the placenta might perhaps have passed muster ten or fifteen years ago.

The epiblastic origin of the pronephric duct is treated as an established fact, and the vertebrate kidney tubule compared to the nephridium of the annelids.

The writer appears to have quite misunderstood the results of recent work on the segmentation of the vertebrate head. On p. 221, for example, it is said that the motor nerve of the fourth cranial segment, comparable, therefore, to the nerves which supply the muscles of the eyeball, is the seventh, and the chorda tympani its sensory root; while the last-mentioned is spoken of here, and in the diagram on p. 35, as pre-spiracular in position, a statement which, however true it may be for some reptiles, is certainly at variance with Broman's careful account of its development in the human embryo.

Again, it would be gathered from the wording on p. 238 that the interventricular septum in Sauropsida is homologous with the similar structure in the mammals; and in chapter xiv. the author has been completely led away by a very dubious theory, to say the least, of the origin of the rods and cones of the retina.

Minor inaccuracies are the ascription of only one dentition to the marsupials (p. 67), the omission of any reference to the possible paired origin of the pineal eye, or to the paraphysis, the derivation of the Eustachian valve from the right valvula venosa alone, and the statement that in fishes the "mesial element" of the diaphragm is alone developed.

Such work as this can hardly be taken as a serious contribution towards the solution of those problems which beset the vertebrate embryologist, and it would have been wiser for Dr. Keith, who appears to intend his book preeminently as a *vade mecum* in the hospital wards, to have resisted the temptation to deal with questions which are beyond the scope and cannot be answered by the methods of mere surgical anatomy. Still, as a practical handbook we hope that this treatise may be a success, especially when, in a future edition, certain orthographical slips—"epiphyseal," "fasiculi," "anastomatic," "systematic" (for "systemic"), "embryoes," "Turicæ" (for "Turcica"), "hypopophysis"—are duly amended.

AN EDUCATIONAL COMPARISON.

The Making of Citizens. A Study of Comparative Education. By R. E. Hughes, M.A., B.Sc. Pp. viii + 405. (London and Newcastle: The Walter Scott Publishing Co., Ltd., 1902.) Price 6*s*.

THE educationist anxious to keep pace with all that has been written on the very wide subject with which he is concerned has had an almost impossible task during recent years. The annual reports of the Commissioner of Education, Washington, are so bulky—the last, that for 1899–1900, runs to 2348 pages—and the special reports of our own Board of Education are published so frequently, that one is tempted to give up in despair the effort to master their contents. In addition to these official publications there are the books written by private persons who have studied foreign methods of education on the spot. Mr. Hughes has, in the book before us, endeavoured to meet this difficulty, and to provide students with "a complete and accurate account of the present position of education in the four principal countries of the world," by which he means England, France, Germany and the United States of America. In the compilation of the volume, free use has been made of the official reports mentioned, and numerous quotations from many writers show that the author has a good knowledge of recent educational literature.

The plan of the book is very simple. After some preliminary pages, separate chapters are devoted to the primary school systems of each of the countries under comparison; after this a general view of the working of primary schools is followed by an account of higher elementary schools. The secondary schools of the four countries are allotted a chapter each, and the book is completed by a *résumé* of the provisions made for the education of girls and for the training of defective children.

With the wealth of material he had from which to select, it was not to be expected that Mr. Hughes would please everybody; naturally the same subjects do not appear of equal importance to all authorities. For instance, in our opinion too little attention is paid to the question of the science teaching in the schools described. The prominence given both in England and America to the need for rational methods in the teaching of science, and to the desirability of the inclusion of some instruction in the methods of science in schools of every grade, is scarcely mentioned by Mr. Hughes. We are told that the science side and master of the best English secondary schools are only tolerated (p. 307), and that chemistry is the favourite and first science taken up (p. 320), though it does not seem to be mentioned that this preference for chemistry as the initial science study is less marked year by year. It is pointed out that the German teacher relies upon the lecture rather than upon the laboratory method (p. 253), that the heuristic method is becoming the accepted way of teaching science in American high schools, and that in them it is usual to begin with the study of physics (p. 280); but these odd paragraphs exhaust all that is said on this important subject.

In view of the influence which science has exerted upon manufacture, commerce and thought generally, a careful comparison of the place which science teaching takes in schools of every grade in the four countries concerned would have been most valuable. The book is intended, however, for the ordinary person with a general interest in education, and this may explain why Mr. Hughes has given more prominence to administrative matters than to questions of curriculum. It only remains to be said that the author's personal acquaintance with English education and his wide experience of schools have enabled him to bring together in convenient compass very much of interest and importance about American, French and German systems of education.

OUR BOOK SHELF.

Animal Forms: a Second Book of Zoology. By David S. Jordan, M.S., M.D., Ph.D., LL.D., President of Leland Stanford Junior University, and Prof. Harold Heath, Ph.D. Pp. vi + 258; 140 figs. and frontispiece. (London: Hirschfeld Bros., Ltd., 1902.) Price 6*s*. net.

THIS attractive volume, distinguished by the freshness and excellence of its illustrations, is designed as "a second book of zoology," "to meet the needs of the beginning student of zoology." The opening chapters deal, somewhat lightly, with the characteristics of living things and of animals in particular, and with the cell and its protoplasm. They are clear and straightforward, but they lack both distinction and distinctiveness. If this sort of introduction is desirable it should be less easy-going.

The bulk of the book consists of a description of the classes of animals, with particular reference to representative types, considered mainly in their structural aspects, but with considerable attention to functions, habits and life-history—always in a simple, elementary fashion. Here and there throughout the chapters the student is judiciously pulled up for a moment before one or other of the deeper problems of biology, *e.g.* the plasticity of form in sponges, regeneration in worms, and the origin of species. Apart from the relative prominence given to "ecology," the absence of anything suggestive of a cramming synopsis and the really fine illustrations, the survey does not differ markedly from that to be found in a crowd of other books.

It is very important that a simple work of this kind should not give the student any impressions which he will afterwards have to discard; therefore we doubt the wisdom of speaking of the "skull" of cuttlefishes, the "external" skeleton of echinoderms, the "gills" of the lancelet, the air-bladder as "a modified or degenerate lung." With such a graphic illustration of the viscera of the starfish, it seems a pity that a "twentieth century" text-book should retain the absurd terms "cardiac" and "pyloric" for the two main regions of the gut. As we should expect from the authors, such blemishes are very rare. We have to lament, however, that the desirable prominence given to "ecology" seems to have practically excluded the good old-fashioned lessons on homology, which we believe to be very useful to "the beginning student," and might also expect in a book entitled "Animal Forms." Another defect seems to us to be the relative absence of the definite suggestion of problems for the student to think over.

The half-tone illustrations, many from photographs, deserve great praise. We may notice, in particular, the murres on the frontispiece, the piddocks in their holes, the long-eared sunfish, the rattlesnake, the raccoon and the baby orang-utan. J. A. T.

Das botanische Practicum. Von Dr. Eduard Strasburger. Vierte umgearbeitete Auflage. Pp. l + 771. (Jena: Gustav Fischer, 1902.) Price Mark 20.

THE third edition of this well-known book has been so favourably received that a fourth edition has now been published. The alterations and additions in this new issue are not so extensive as in the previous one, but they are nevertheless considerable, and the whole book has been subjected to careful revision. The scope of the book has certainly advanced beyond the author's original intention as conveyed by the title, "Introduction to the Personal Study of Microscopic Botany," for there are references to several important facts which are highly interesting, but the experiments connected with them one would not think of undertaking unless they formed part of an original investigation; parthenogenesis in Marsilia and the problem of intramortal or intravital staining are notable instances. As the facts are stated without critical opinions being offered, a simple reference to the publications would have been as valuable, and would have made a reduction even though slight in the size of the book. However, the greater number of the additional paragraphs are of considerable practical value, and not the least so are the directions or hints which emanate from Prof. Strasburger himself or from workers in his laboratory, as, for instance, the method of examining the root of *Vicia Faba*, the directions for embedding small algæ and the instructions for demonstrating protoplasmic threads (Plasmodesmen). Other notable additions include new tests for starch, fats, callus and cork, and the use of neutral violet as a reagent for pectic compounds. Darwin's device of using hornshavings as a hygrometer to determine the number of stomata and Buscalioni's collodion method for the same purpose are mentioned, and some account is given of Brown and Escombe's work on the diffusion of gases through small apertures. It will be found that this edition differs mainly by the insertion of new paragraphs, and practically the only chapter which is rewritten is the last, dealing principally with cell problems.

Principles of Sanitary Science and the Public Health. By Prof. William T. Sedgwick, Ph.D. Pp. xix + 368. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 12*s*. 6*d*. net.

A FEW sentences of the preface to this work serve admirably to indicate its scope and, it may be added, its attainment. "This volume deals with the principles, rather than the arts, of sanitation," the author writes. "It is intended to be no more than an elementary treatise on the subject; and while it is believed that it contains some new material, and some old material treated from new points of view, no special claim is made for originality either in substance or in method of presentation." The author has, therefore, chiefly sought to bring together and to present in a simple and logical form those fundamental scientific principles on which the great practical arts of modern sanitation securely rest.

If the chapter on disinfection is taken, that will serve well to illustrate the scope and limitations of the work. There the necessity for disinfection and the object of disinfection are dealt with, but no directions are given as to how principles are applied in actual practice.

It is a most readable work, in which every principle of sanitation that is enunciated is lucidly explained and convincingly advocated, and in which the history of the facts on which the principles of sanitation are based is brought right up to date. It is a good book for everyone to read, and there is certainly no better book for the student to master before he commences the study of the practical and administrative side to public health work.

The author is very sound in his opinions. It is necessary to aim at high ideals when one advocates preventive measures in the interest of the public health, for those measures which are generally thought to be extreme are frequently the only ones which attain their object; but the author's ideal of a city, the water-supply of which is derived from surface-water, owning the entire watershed and keeping it clean and uninhabited, is an impossible one. Even in America it must be rare indeed that a city can secure for its water-supply a totally uninhabited watershed; but everyone will agree that a systematic and frequent inspection should always be maintained to guard the purity of the water collected on such gathering grounds. It is one of the great reproaches upon the sanitary administration of this country that so little is done in this direction. Frequently one sees men employed to patrol river banks to guard the interests of those who have the sole right to the fishing, while no systematic inspection is carried out to guard against

dangerous pollution of the water in the higher interests of the public health.

The work is a welcome addition to public health literature, and it is sure to meet with general appreciation. It should appeal to a wide circle of readers, for it is written in a manner which presents a most important subject in a clear and intelligible light to everyone.

Nature Study: Realistic Geography. Model based on the 6-inch Ordnance Survey. Designed by G. Herbert Morrell, M.A. (London: Edward Stanford.) Price 3*s.*

THIS is a model of the country round Streatley-on-Thames, constructed by cutting out pieces of cardboard according to the contour lines and placing them one above another in the positions shown by the map. Spare pieces of cardboard, on which the contour lines are printed, ready for cutting out to make a second model, are enclosed in a portfolio along with the first. The construction of models of this kind has been carried out for some years in a number of schools, both in this country and abroad, but the general experience seems to be that, like the trigonometrical survey of the school and playground, and other similar devices, the time necessary to carry them out is too much for the value of the results obtained. The use of Mr. Morrell's model undoubtedly saves some time, inasmuch as the contour lines are already traced, but we suspect that the tracing of the contour lines is really the most important part of the exercise. But anything which assists in familiarising British school children with the ideas of contour lines and surfaces is to be welcomed; it is astonishing how many children who are familiarly acquainted with isobars, isothermals and "iso-" lines of all sorts have scarcely heard of contour lines, and it is not too much to state that the failure to present the conception of a contour or "iso-" line as the intersection of a surface with the surface of the earth is almost the fundamental defect in our teaching of advanced physical geography. Apart from its application to the purpose for which it is immediately intended, Mr. Morrell's model should be of value to teachers for demonstration.

A Junior Chemistry. By E. A. Tyler, B.A. Pp. viii + 228. (London: Methuen and Co., 1902.) Price 2*s.* 6*d.*

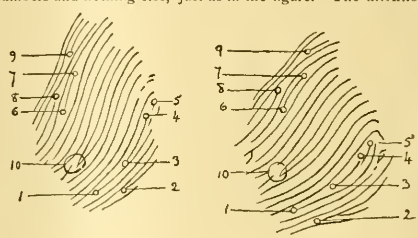
THE author's primary object seems to be to enable boys to present themselves successfully for the examinations in chemistry held in connection with the Oxford and Cambridge locals and similar examinations. He recognises the existence of a better way of teaching his subject than the one he adopts, and urges in extenuation of his procedure the inadequate provision made for practical science in most secondary schools and the small amount of time devoted to science in them. Mr. Tyler expresses the hope that the book he has written will enable boys in ordinary schools "to acquire, as far as possible, a scientific knowledge of chemistry," but he does not seem to understand that science is not properly included in the curriculum because of the information its study imparts, but rather as a means of developing a habit of mind. Unless chemistry is studied experimentally, and is made to train the pupil to observe and to reason from his observations, it has no right to a place on the school time-table. Before the pupil has been set to study the preparation and properties of a few simple substances, and from his own deductions taught to discover the laws of chemical combination, Mr. Tyler tries to explain to him the atomic theory, Avogadro's law, compound radicals, and other theoretical considerations. Though the author understands well enough all the chemistry a boy need learn at school, he does not quite appreciate why men of science desire such subjects as chemistry to be introduced into school work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Finger Print Evidence.

BY the courtesy of authorities in Scotland Yard, I have just received duplicates of two enlarged photographs (on slightly different scales). These photographs were lately submitted in a court of law to prove the identity of *a*, the mark left on the window frame of a house after a burglary had been committed, with *b*, the impression of the left thumb of H. J., a criminal then released and at large, whose finger prints are preserved and classified in Scotland Yard. I wished to show the resemblance between *a* and *b* by the method described in my "Decipherment of Blurred Finger Prints," believing that to be the readiest way of explaining to a judge and jury the nature of the evidence about to be submitted to them. I send the results. The questions of the best mode of submitting evidence and of the amount of it that is reasonably required to carry conviction deserve early consideration, for we may have a great deal of it before long. It is as a contribution towards arriving at a conclusion that I send the enclosed. I should say that in the above-mentioned book, each pair of impressions was printed in triplicate and on a still larger scale than these. One of the three was untouched, the second had lines drawn like those in the figure, down the axes of the ridges, the third had the lines and numbers and nothing else, just as in the figure. The attention



a *b*

of the judge and jury could be easily directed by counsel to whatever pair of corresponding points he might desire, by reference to their common number on the chart. Without some such guidance it would be extremely difficult to do so, for persons unaccustomed to finger prints are bewildered by the maze of their lineations.

Certain more or less faint lines run across *a* that seem to have been made with the brush when painting the window frame. They seriously interfere with the lineations just above No. 5 and to the right of it. No. 5 is itself so far affected by them that I do not attach full weight to it as a point of reference. But accurate comparison is possible at nine other points, all of which are marked, and a close agreement will be found between every pair of them as well as in the number of intervening ridges.

FRANCIS GALTON.

[The prints have been too much reduced from the tracings I sent, to be quite clear. Thus unless a lens be used, No. 2 in *b* will probably be misinterpreted.]

Remarkable Fossil Oysters from Syria.

IN examining a series of more than one hundred specimens of *Ostrea* (*Exogyra*) *flabellata*, Goldfuss, from the Middle Cretaceous of Lebanon, I was struck with the marked reproduction in the free upper valves of the figures of other shells to which the lower valves have been attached. These specimens were all collected in the same place, a hill near Bḥamdûn, Mount Lebanon, Syria. They have been freed by weathering from a soft marly rock exceedingly rich in fossils. Specimens of Ostrea, Plicatula, Pecten and Anomia have the shell well preserved. Many others, including species of Cardium, Trigonia, Corbula, Isocardia, Cytherea, Leda, Nucula, Cerithium, Alaria, Melo, Pterocera, Turritella, Natica and others are preserved only as casts. Consequently the shell to

which the oyster was attached has usually disappeared, except in those cases in which it was attached to one of its own species. More than half of the specimens have the two valves united and free from adhesions, so that they are capable of exhibiting the phenomenon referred to. More than nine-tenths of these show more or less clearly in the upper valve the figure impressed upon the lower valve by the shell to which the latter adhered.

In most cases this is the figure of a part of the outer surface of a bivalve shell. In a few it is the inner surface of a bivalve shell. In one oyster the figure of part of a specimen of *Cerithium magnicostatum*, Conrad, is clearly shown above and below; in another, *Cerithium libanoticum*, Fraas, with a much better outer lip than is usually found in specimens of the original shell. In two cases the internal cast of a small Cerithium, together with some of the matrix, still adheres to the lower valve of the oyster, while its external form, lost below, is beautifully reproduced upon the upper valve.

In two very striking instances, the lower valve of the oyster shows the impression of a bivalve shell with spiny ribs, while a reproduction of these same spiny ribs appears in high relief upon the upper valve. These reproductions in the upper valve of figures impressed upon the lower valve might be supposed to result from the close contact of two valves when both valves were thin and small, and might be expected to be confined to the region of the umbo in well-grown specimens; but in all cases in which the oyster has been attached by a large portion or all of the lower valve, the impression is reproduced upon a correspondingly large portion of the upper valve. In view of the fact that in most specimens the shell is from 1·5 to 2 cm. thick, and, further, that internal surfaces when exposed show no traces of these external markings, it is noteworthy that the markings should extend over so much of the upper surface instead of being confined to the umbonal region.

ALFRED ELY DAY.

Syrian Protestant College, Beirût, Syria, September 22.

THE peculiar phenomenon referred to in the above letter is well known to occur among Secondary fossils, and has been fully explained by Prof. J. W. Judd in the *Geological Magazine* for 1871, p. 385, where several figures of Oolitic forms are given in illustration. The same peculiarity is also seen in certain oysters from the Lias. The thin growing edge of the shell adapts itself to the inequalities of the surface upon which it grows; the upper valve, being also thin, reproduces the form of the lower valve. The shell becomes thickened by additional layers on the inside, which thus gradually loses the markings that are retained upon the outer surfaces. E. T. N.

Refractivities of the Inert Gases.

A RELATION appears to exist between the refractivities ($\mu-1$) of the inert gases of the atmosphere and that of hydrogen, which, so far as I am aware, has hitherto escaped attention. The following figures show that, taking the refractivity of hydrogen as 1, the refractivities of the other gases are very nearly in the proportion of $\frac{1}{4}$, $\frac{1}{2}$, 2, 3 and 5.

By far the largest divergence is in the case of helium. This gas, as I am informed, is difficult to purify from the admixture of the heavier gases, so that a perfectly pure specimen would probably give a better result. Even if the relation to hydrogen is fortuitous, the ratios of the refractivities of the other five gases to one another are sufficiently interesting.

Refractivities[1] observed (Air=1).		Ratio to H.	Calculated from H=0·4733.	Error per cent.
Helium	0·1238	$\frac{1}{4}$	0·1183	−4·4
Neon	0·2345	$\frac{1}{2}$	0·2366	+0·9
Hydrogen	0 4733	1		
Argon	0·968	2	0·9466	−2·2
Krypton	1·450	3	1·420	−2·0
Xenon	2·364	5	2·367	+0·1

CLIVE CUTHBERTSON.

9 York Terrace, Regent's Park, N.W., October 10.

[1] Ramsay and Travers, *Phil. Trans.*, vol. cxcvii. A, 1901, p. 47.

Trade Statistics.

IN his reply to my letter (October 2, p. 550), Dr. Mollwo Perkin brings forward fresh figures, apparently proving an enormous decline in British industry since 1870–74. This, however, is but to repeat Mr. Levinstein's mistake in an aggravated form. The Franco-Prussian war in 1870 checked manufacturing abroad for a twelvemonth, and in 1870–74 there was a heavy demand for British iron and coal at excessively high prices. That period, as is well known, is useless for comparisons of British and German export trade.

It is true, as Dr. Perkin points out, that the general rate of increase of exports (*i.e.* of their total values irrespective of the number of producers) has, in the last twenty years, been very slow in this country, rather rapid in Germany and very rapid in the United States.

But if we reckon per head of population, we get the following (from the Board of Trade "Memorandum," "Cd. 1199"):—

Annual Exports ("Special") per head of Population.

Average of period.	United Kingdom.	France.	Germany.	United States.
	£	£	£	£
1875–79	6·00	3·75	3·15	2·81
1880–84	6·66	3·67	3·43	3·30
1885–89	6·18	3·46	3·27	2·59
1890–94	6·15	3·57	3·14	2·95
1895–99	5 97	3·73	3·36	2 92

These figures are distinctly reassuring. They must not be used as an excuse for laxity in education or the application of science to manufacture, but they ought to allay unreasonable pessimism.

The slight decline per head in the British exports (as measured in money, not in commodities) would be a rather unsatisfactory feature if the export trade were our chief trade and chief source of income. Dr. Perkin perhaps thinks that it is, for he translates Mr. Levinstein's "foreign trade" into "trade." But the gross value of the export trade (280 or 300 millions per annum), large as it is, is small compared with the total national income, recently estimated by Sir Robert Giffen at 1500 millions sterling, while the income-tax assessments indicate that it is increasing faster than the population (*Times*, May 23, 1901). This enormous income is, of course, chiefly made up of the value of goods produced and consumed within the country, constituting the internal trade as distinguished from the foreign trade. From this point of view a close scrutiny of export statistics appears to be unnecessary, and may easily be misleading.

Unfortunately, we have no adequate statistics of total production. The figures for pig iron which Dr. Perkin gives are to the point, and the progress of our two great rivals is here very striking. But the pig-iron manufacture accounts for less than 3 per cent. of our national earnings. F. EVERSHED.

Kenley, Surrey, October 10.

Material for Natural Selection.

Verbesina exauriculata[1] is an evil-scented but handsome herbaceous plant with broad orange rays, very abundant in the town of Las Vegas, New Mexico. My class in biology has been making a study of the variations in the number of rays in the heads of this plant, and in so doing we took occasion to compare two sets, from the eastern and western parts of the town respectively. The result was as follows, calling these sets A and B respectively:—

Number of Rays.	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)	(15)	(16)	(17)	(18)	(19)	(20)	(21
Number of heads, set A.	—	—	7	7	31	63	96	30	19	13	7	9	7	3	2.
Number of heads, set B.	1	6	10	19	32	73	84	25	12	5	2	1	—	1	—.

[1] *Verbesina encelioides exauriculata*, Robinson and Greenman, *Proc. Amer. Acad.*, May, 1899, p. 544. Notwithstanding the name of this northern type, the petioles of the upper leaves are commonly strongly auriculate.

It will be seen that the mode is the same in each case, but the means are very different. To ordinary observation, the two sets of flowers looked exactly alike, and the demonstration of a difference in the average, while not at all extraordinary, is interesting. No doubt such differences exist in all organisms and all characters, and one can easily see how, under certain circumstances, they may have an important bearing upon the question of survival. The great variability no doubt indicates that the number of rays is *not* at present of much importance to the Verbesina; and no doubt those organs which have become variable for this reason, but suddenly become of importance through changed conditions, afford the best material for selection. In other words, evolution will proceed fastest when there are changes in the survival-value of organs. While examining the Verbesina, I found on the undersides of the leaves a new species of spinning mite (*Tetranychus verbesinae*); a little creature about half a millimetre long, pale yellowish, with two scarlet spots on the anterior part of the body, and irregular black spots (pertaining to the soft parts) arranged somewhat in the form of a crescent. The first pair of legs is somewhat more than half the length of the animal; mandibular plate with the sides as in *T. gloveri*, but the end rounded; hairs of body moderate, on very small tubercles. Further particulars will be given elsewhere.

T. D. A. COCKERELL.

East Las Vegas, New Mexico, U.S.A., September 17.

THE INTERNATIONAL METEOROLOGICAL COMMITTEE.

IF we come to consider the work of the International Meteorological Committee and its predecessor, the Permanent Committee of the Vienna Congress, it will be impossible to deal with the subject without taking notice of all the meetings, whether Congresses or Conferences, from which the committees above named took their rise.

It may here be explained that Congresses are convened through diplomatic channels; Conferences are brought together by private invitation to meteorologists of repute.

The first attempt to convene an international meeting was in 1845, when a Conference was held at Cambridge on the occasion of the meeting of the British Association in that year. This was attended by Dove, Kupffer, von Lamont, Adolph Erman and some other foreigners, and of course by the leading meteorologists of England. The difficulties in introducing uniformity in land observations were found to be too serious for definite arrangements to result.

This was followed, in 1853, by the Brussels Conference, which was instigated by Maury. It dealt with the Meteorology of the Sea, and its action met with general acceptance among maritime nations. It may be said that our own Meteorological Office was an outcome of this Conference.

In 1863 Dove endeavoured to convene a Conference on Land Meteorology. At the meeting of the Swiss Naturforscher Verein, he invited the meteorologists of Austria, France, Italy and Spain, but the invitation was not generally accepted.

Nothing definite, however, was done for Land Meteorology until Weather Telegraphy took its rise, about the year 1860, when the demand from each nation for regular intelligence from adjacent countries rendered it impossible for any Government to ignore the subject absolutely. Still, however, every country continued to deal with its Climatology as seemed right in its own eyes.

This was the state of affairs when, in 1872, Profs. Bruhns (Leipzig), Jelinek (Vienna) and Wild (St. Petersburg) issued a general invitation to a Conference, to be held at Leipzig coincidently with the meeting of the German Naturforscher Verein. This Conference was a signal success. It was attended by 52 members, and from it all subsequent meetings took their rise.

There have been in all seventeen of these meetings.

1872. Leipzig, Conference.
1873. Vienna, Congress.
Do. First meeting of Permanent Committee.
1874. London, Maritime Conference.
Utrecht, meeting of P.C.
1876. London, meeting of P.C.
1878. Utrecht, meeting of P.C.
1879. Rome, Congress.
1880. Berne, meeting of Int. Met. Committee.
1882. Copenhagen, meeting of I.M.C.
1885. Paris, meeting of I.M.C.
1888. Zurich, meeting of I.M.C.
1891. Munich, Conference.
1894. Upsala, meeting of I.M.C.
1896. Paris, Conference.
1899. St. Petersburg, meeting of I.M.C.
1901. Paris, meeting of I.M.C.

An elaborate *résumé* of the resolutions at all the meetings, down to the Munich Conference, was printed by the late Prof. Wild in vol. xvi. of his "Repertorium für Meteorologie."

In dealing with the action taken at these several gatherings, it is found that many of the resolutions passed at early meetings were materially modified on subsequent consideration, and this is especially the case with reference to instruments and their observation. It is therefore proposed to mention only the final outcome.

The Barometer.—The use of aneroids as independent instruments was condemned, and it was decided that all standard barometers, at Central Offices, should be compared with the standard barometers of the Bureau International des Poids et Mesures at Paris.

As regards barometer corrections, the readings in climatological tables are to be given unreduced to sea level. It is desirable to apply the Gravity correction, and at all events it is to be stated in the tables if this correction has been applied or not, and what is its amount.

The Thermometer.—In this case too the standards at Central Offices are to be compared with the standard air thermometer of the Bureau International.

No recommendation has been made on the subject of thermometer exposure, owing to the impracticability of meeting the requirements of all climates. Meteorologists are referred to the published papers on the subject by Wild and others.

The desirability of devising a really good maximum thermometer was expressed. As regards minimum thermometers, the use of amyl alcohol instead of ordinary spirit was recommended.

Maximum and minimum thermometers are to be read at the latest observing hour of the day.

Humidity.—This subject was treated at considerable length, and the employment of ventilation with the wet bulb was urgently insisted on. At the meeting of St. Petersburg, Prof. Pernter proposed to abandon the use of the dry- and wet-bulb hygrometer, and to revert to the use of the hair hygrometer, but the proposal was not adopted.

Wind.—No general form of anemometer was recommended, nor was any action taken as to uniformity of installation or of altitude. As to wind direction, the English letters N. E. S. W. were adopted owing to the misunderstandings caused by the use of "O" for "Ost" in German and for "Ouest" in French.

Clouds.—At the Munich Conference, the international scheme of Cloud Observations, Direction and Velocity, for one year, was adopted, and the results of this work have appeared. At the same meeting, the Classification of Clouds proposed by Abercromby and Hildebrandsson was adopted, and from that has come the "International Cloud Atlas."

Rain.—It was decided to place rain gauges in such positions as should preclude their being buried in snow or exposed to splashing from the ground. It was recommended to mark especially the days of precipitation which did not reach the limit of 1 mm. and to ignore falls below 0·1 mm. Two columns are to be given

for Snow, one for amount, and the other for depth on the ground.

Unusual Occurrences.—The well-known international symbols were adopted at the Vienna Congress.

Glaciers.—A general recommendation was made to institute measurements of the motion of Glaciers.

Earth Movements.—The statements of Monsieur de Rossi, at Rome, as to what he terms "la météorologie endogène" were received with much interest.

As regards other matters, various combinations of hours for observing were suggested.

The simultaneous observations, proposed at Vienna, by the Chief Signal Office of the United States, were strongly supported.

As regards Weather Telegraphy, an international code for the messages was adopted and various details were settled.

The International Forms for the publication of climatological data (stations of the Second Order) were all arranged and have been very generally adopted.

Among the most lasting and valuable results of these gatherings has been the volume of International Tables, published by Gauthier Villars in 1890.

At several meetings endeavours were made to organise an International Office for directing international work, and this resulted in a proposal for an International Directing Bureau. This scheme, however, failed to secure approval. Various resolutions were framed as to international investigations.

The whole scheme of International Balloon Ascents, superintended by Prof. Hergesell, of Strassburg, took its origin at the Paris Conference of 1896.

The Circumpolar Observations of 1882–3, on the scheme of the late Lieutenant Weyprecht, also took a definite shape at the Roman Congress.

Terrestrial Magnetism.—This subject was first discussed at the Munich Conference in 1891, and at the Paris Conference of 1896 a special committee *ad hoc* was appointed, under the presidency of Sir A. Rücker, and in the report of that conference its action can be seen.

R. H. S.

JOHN HALL GLADSTONE.

THE scientific world has lost an indefatigable worker by the sudden death of Dr. Gladstone, which occurred on Monday, October 6. Few men had a larger circle of friends, for the beauty of his character and the kindliness of his nature endeared him to all those who had the good fortune to know him.

Dr. Gladstone was born in London in 1827, and was educated at University College, London, and Giessen University. He was twice married, first, in 1852, to May, daughter of the late Charles Tilt; and secondly, to Margaret, daughter of the late Rev. D. King and niece of Lord Kelvin. So early as 1850 he became lecturer on chemistry at St. Thomas's Hospital, and three years later (in 1853) he was elected a Fellow of the Royal Society. He served on its Council in the years 1863–1864 and again in 1866–1868, and a few years ago received the Davy medal. The Royal Society list of papers credits him with more than a hundred contributions to scientific literature, apart from those in collaboration with other writers. He held the Fullerian professorship of chemistry at the Royal Institution from 1874 to 1877, was first president of the Physical Society from 1874 to 1876, and was president of the Chemical Society from 1877 to 1879.

There can be no question, as an eminent English physicist has recently pointed out, that Dr. Gladstone was "one of the founders of physical chemistry, a fact which is fully recognised abroad, where his rightful position is accorded him." It is, however, only necessary to show how highly his work was appreciated in England to quote the reference to it which was made in 1898, on the occasion of a banquet to past presidents of the Chemical Society who had been Fellows of the Society for half a century, of whom Dr. Gladstone was one. Prof. Dewar then said, "Gladstone has worked out his long and brilliant scientific career as a labour of patient love. Furthermore, he has created an entirely new department—that which is in modern times regarded as physical chemistry. For half a century he has worked on this side of chemistry, for his early investigation of the spectrum of the atmosphere was one of marvellous suggestiveness. He found that the spectrum of Fraunhofer varied at sunset and at sunrise from that at midday, and showed that a large number of those absorption lines must originate in the earth's atmosphere. That discovery stimulated further inquiry as to the substance that could produce these lines so characteristic of the solar atmosphere; and later experimenters have found it in the vapour of water and in oxygen. Gladstone's greatest merit, however, lies undoubtedly in his optical researches on the atomic refractions and dispersions of the elements. He has determined the optical constants of hundreds of bodies, and has thus stimulated inquiry in that borderland between physics and chemistry which is so much cultivated in the present day, and the pursuit of which has added so much to our knowledge. He has also contributed largely to miscellaneous inquiries, especially those connected with various voltaic batteries, and other questions conducive to the study of both organic and inorganic chemistry."

His work was remarkable for its very varied nature. The title of his first paper was "Contributions to the Chemical History of Gun-cotton and Xyloidine," and, true to this early promise, he served as a member on the Gun-cotton Committee of the War Office from 1864 to 1868, having previously served as a member of the Royal Commission on Lights, Buoys and Beacons (1858–1861). Among his less known work, his investigations in connection with early metallurgical history well deserve mention. For instance, he showed that the use of bronze in Egypt went back as far as 3700 B.C., and that not only was bronze used, but that it was of a type common to much later periods, the ratio of copper to tin being as 9 to 1.

It is as an educational reformer that many of Dr. Gladstone's friends will best remember him, for he worked hard for twenty-one years, beginning in 1873, as a member of the London School Board, upon which body he represented the Chelsea division, and was for three years its vice-chairman. He was unwearied in his insistence upon the necessity for teaching science in elementary schools, keeping steadily in view its influence upon the nation as a whole. His attitude may best be gathered from the concluding sentence of his presidential address delivered before the members of the Chemical Section of the British Association in 1872. It ran as follows:—"While the rudiments of science are being infused into our primary education, now happily becoming national, while physical science is gradually gaining a footing in our secondary and our large public schools, and while it is winning for itself an honoured place at our universities, it is to be hoped that many new investigators will arise and that British chemists will not fall behind in the upward march of discovery, but will continue hand in hand with their continental brethren, thus to serve their own and future generations."

The prevailing ignorance of science and scientific methods is constantly rebuked by modern educational writers, but a sentence such as the following, which also occurs in Gladstone's presidential address in 1872, was unusually plain speaking for twenty years ago. He says "the so-called educated classes in England are not only supremely ignorant of science, they have scarcely

yet arrived at the first stage of improvement—the knowledge of their own ignorance."

Among the glowing tributes to Gladstone's memory which have been offered since his death, none are more significant than the following words from one who is singularly well qualified to form an opinion as to the value of his educational work. "It is twenty years," the writer says, "since I first made his acquaintance as a co-worker on my election to the London School Board, and the respect which I felt at first for his activity and devotion in the cause of London education soon ripened into a real personal affection and warm admiration for his unselfish and kindly nature and for his insight into the needs of children intended for industrial life. He was almost the first to see that elementary education must be widened to include the training of all the faculties if it is to be effective, and he did more than any to bring this knowledge to a practical result. It would be well for the country if more men existed of the same noble character."

He has left many witnesses to his power of influencing young scientific workers, to many of whom his memory will be very precious, for but few men have been so faithful throughout a long life to high ideals, and have at the same time so effectively promoted the welfare of humanity.

W. C. R. A.

NOTES.

THE subject of the address of the retiring president (Dr. E. W. Hobson, F.R.S.) of the London Mathematical Society at the annual general meeting on Thursday, November 13, at 5.30, will be "The Infinite and the Infinitesimal in Mathematical Analysis." There are few people better qualified than Dr. Hobson, both on the mathematical and the philosophical side, to expound the change of view that has been gradually spreading over the field of advanced pure mathematical thought during the last half-century; and many persons interested in the subject will doubtless take advantage of his explanations who would not have time to make headway with the extensive literature, mainly foreign, to which these modern philosophical developments have given rise. At the same meeting, the triennial De Morgan medal will be presented to Prof. A. G. Greenhill, F.R.S., for his contributions to mathematical analysis and its application to mechanical problems.

WHILE attempting to navigate the air with a new steerable balloon, M. de Bradsky and his assistant, M. Morin, were killed at Stains, near Paris, on October 13. The balloon was so constructed that the weight of the gas and all its parts was about equal to the weight of air displaced, so that it remained at rest until the propelling screw was started. The screw was driven by a 16 horse-power motor and was behind a steel car, seventeen metres long, suspended by steel wires attached to a light wooden scaffolding. After the balloon had started, it was evident to the spectators that the motor power was insufficient to enable it to be steered. When at an altitude of about one hundred metres, the car broke away from the balloon and was dashed to the ground, causing the death of the two occupants—M. de Bradsky and M. Morin. The disaster appears to have been caused either by the fracture of the steel wires by which the car was suspended from the envelope, or by the whole framework slipping away from the balloon.

ON Friday, November 7, Lord Kelvin will reopen the ancient Cloth-hall at Newbury, which has been restored as a memorial to Queen Victoria and will in future be utilised as a local museum and art gallery.

THE committee of the Huxley Memorial at Ealing has had a memorial tablet placed in the Free Library, Walpole Park, and it will be unveiled by the Mayor of Ealing, on behalf of the Borough Council, on October 23 at 4 p.m.

THE annual "Fungus Foray" of the Essex Field Club will be held on Friday and Saturday, October 17 and 18—in the country near North Weald and Foot Hill on the Friday, and on the Saturday in Epping Forest. Botanists desirous of attending should communicate with the hon. secretary, Mr. W. Cole, Buckhurst Hill, Essex.

WE learn from the *Times* that an interesting antiquarian discovery has just been made in the neighbourhood of High Wycombe in connection with the construction of the new main line of the Great Western and Great Central Railway Companies. In the course of excavating a hill an ancient flint mine has been unearthed, together with an interesting specimen of a pick made of the antler of a stag with its points worn smooth. Many of the disintegrated blocks bear the marks made by the picks used by prehistoric workmen.

THE council of the Institution of Civil Engineers has, in addition to the medals and prizes given for communications discussed at the meetings of the Institution in the last session, made the following awards in respect of other papers dealt with in 1901–1902:—A Telford gold medal to Mr. J. Macfarlane Gray; a George Stephenson gold medal to Mr. R. Price-Williams; a Watt gold medal to Dr. W. Bell Dawson; Telford premiums to Mr. W. R. Cooper, Mr. E. M. De Burgh, Dr. George Wilson, Mr. Frank Oswell and Dr. A. W. Brightmore; a Crampton prize to Mr. C. D. H. Braine; the Manby premium to Mr. B. W. Ritso. For students' papers the awards are:—A Miller scholarship (tenable for three years) and the James Forrest medal to Mr. H. F. Lloyd; Miller prizes to Messrs. J. C. Collett, W. H. C. Clay, H. C. M. Austen, A. M. Arter, Robert Bruce, L. F. Wells and W. H. McLean.

PROF. ROBERT WALLACE is preparing for publication the "Reminiscences" of the late Miss E. A. Ormerod, to the preparation of which she devoted the leisure of her later days. The autobiography was not completed, and much additional material of an interesting character must be in existence. Prof. Wallace would be glad to receive such letters from Miss Ormerod as her correspondents may consider of sufficient importance, together with any other information which they think will be of interest to the general public. His address is the University Edinburgh.

THE remarkable successes achieved by the Marconi system in transmitting messages from Cornwall, across the continent, to the *Carlo Alberto*, moored off the coast of Italy, are well known; some further details of the experiments were published in the *Times* of October 14, from the official report upon them. It appears from this report that the magnetic detector, recently described by Mr. Marconi before the Royal Society, proved in every way superior to the coherer. It was much more accurate in its working and required no regulation. Moreover, it was less sensitive to atmospheric disturbances, giving fairly clear signals under conditions which put the coherer *hors de combat*. The experience on board the *Carlo Alberto* also served to confirm the observation that signalling was more difficult during the day than the night, but this only necessitates increasing the power at the transmitting station in order to carry on long-distance work continuously; there seems to be a practical limit to the sensitiveness of the receiver in that it must not be made too easily affected by atmospheric influences.

THE subject of this year's essay competition for the prizes o. 10*l.* and 5*l.* annually offered by the Society for the Protection of Birds (3 Hanover Square, W.) is "Birds in the Field and Garden: their Economic Value to Man." The Society's object is to collect facts and opinions respecting the utility of birds as insect and weed destroyers, a matter which has in recent years compelled attention in various parts of the world, but is still

only very imperfectly understood and appreciated. Full particulars may be obtained from the hon. secretary.

THE Huxley memorial lecture was delivered on October 1 at the opening of the Charing Cross Hospital Medical School by Prof. Welch, of the Johns Hopkins University, whose discourse was entitled "Recent Studies of Immunity with Special Reference to their Bearing on Pathology." After a tribute to the memory of Huxley and of Virchow, Prof. Welch proceeded to discuss the specific properties of the cells and fluids of the body in health and disease in their relation to immunity, referring to the various antitoxic, bacteriolytic, hæmolytic and cytolytic functions exerted under certain conditions. He pointed out that whereas the tetanus and diphtheria bacilli elaborate toxins which can be separated from the organisms that produce them, such is not the case with other pathogenic bacteria, notably the typhoid bacillus, the toxin of which is believed to be intracellular and intimately associated with the bacterial cells. On this conception, the disease symptoms present in typhoid fever are assumed to be due, not to the living and vigorous organisms, but to typhoid bacilli which have died and in consequence have set free their protoplasmic poisons. Prof. Welch doubts whether this theory affords a complete explanation of the toxic phenomena in typhoid and other similar infections, and advances an ingenious alternative hypothesis. The injection of bacterial cells stimulates certain cells of the host to generate one component of the toxin, the intermediary body, which although itself not poisonous, becomes so by bringing about the union between a pre-existing toxophorous substance, the complement and the foreign cell which started the reaction. Similarly, Prof. Welch suggests that certain substances derived from the host may stimulate the invading organism and cause it to produce intermediary bodies which might have the power to link complements to cellular constituents of the host and thereby to poison the latter. That is to say, just as the cells of the organism react towards the invading bacterium, so Prof. Welch suggests does the bacterium react towards the cells of the host, a possible factor hitherto overlooked. Finally, it was pointed out that such researches as these can be carried out only by the experimental method, and that to impose unnecessary restrictions with regard to experiments upon animals is nothing short of a crusade against humanity.

WE have received a valuable series of meteorological results made at Truro for the Royal Institution of that town. The tables are divided into two sets, (1) the monthly values for the separate years 1882–1900, and (2) the average monthly values for fifty-one years, 1850–1900, compiled by Mr. G. Penrose, curator of the Truro Museum. The establishment of the observatory was mainly due to the late Dr. Barham, who prepared the summary for the years 1850–1881. The mean of the daily maximum temperature is 58°·5 and of the daily minimum 44°·7, the extremes being 92° in June, 1893, and 8° in January, 1867. The mean annual rainfall is high, 40·5 inches. It is noteworthy that the Cornwall Institution possesses several long series of observations, dating from those of Dr. Borlase, of Ludgvan, 1754–1772; Mr. James, at Redruth, 1787–1806; Mr. E. C. Giddy, at Penzance, 1807–1827. These are closely followed by Mr. Moyle's, at Helston, and others.

A REDETERMINATION of the density and coefficient of cubical expansion of ice at 0° C. is given by Mr. J. H. Vincent in the *Physical Review*. The author, after comparing previous results, obtains a value agreeing closely with that found by Nichols for the density, but considers that the coefficient of cubical expansion is from 4 to 5 per cent. less than the mean of the previous determinations.

MR. S. J. BARNETT contributes to the *Physical Review* a note on Gauss's theorem, considered mainly with respect to electrostatics. It is pointed out that the ordinary demonstrations apply only to the case of a single homogeneous isotropic medium, and that the theorem is usually implicitly assumed to hold good in all cases. Mr. Barnett now attempts to deduce the generality of the theorem in a logical manner. But in order to extend the validity to a region containing any number of homogeneous dielectrics, or to a medium of varying permittivity, the author has to assume that in a condenser containing two dielectrics, one in contact with one face and the other in contact with the other, the charges on the two faces are equal and opposite. The theorem is thus seen to be based on experimental evidence and not to be capable of proof by deductive methods alone.

FROM the Report of the Survey of India for 1900–1, we notice that surveyors were engaged during the season in the determination of astronomical latitudes in Karachi, while another party was employed with satisfactory results on experimental work connected with the Jaderin base line apparatus. Tidal observations were continued as usual. Preparations for the commencement of a magnetic survey were continued during the year, and arrangements were made for the establishment of base stations at Bombay, Kodaikanal, Dehra Dun, Calcutta and Rangoon, at which magnetic observatories are to be built and self-recording instruments installed. The recent introduction of electric tramways in Calcutta and their impending construction in Bombay have rendered it necessary to arrange for the construction of the new observatories far enough away from the two cities to be beyond the effects of the electric current.

THE Bremer arc lamp, in which the arc is maintained between a pair of inclined carbons saturated with certain mineral salts (see NATURE, this volume, p. 272), has recently been subjected to careful photometric tests by two independent observers, M. Laporte in Paris and Prof. Wedding in Charlottenburg. A full discussion of the two sets of experiments is given in *L'Éclairage Électrique* for October 4. The results are not in very close agreement, though both bring out the superiority of the Bremer lamp over ordinary arc lamps. This is especially noticeable if one only considers the mean hemispherical candle power for the lower hemisphere, since the construction of the Bremer lamp is such that, when used without a globe, practically all the light is thrown downwards. The distribution of light in this direction is also particularly good, being nearly uniform throughout an angle of 50° on either side of the vertical. The consumption of power in a 400-watt lamp comes out at about 0·6 watt per spherical candle and 0·4 watt per hemispherical candle for the Bremer lamp with a globe, as against 1·1 and 0·65 for an ordinary lamp under similar conditions.

WE referred in these columns a short time ago to the fact that an American company had been formed to work a process for the fixation of atmospheric nitrogen. Some further particulars of the apparatus used by the inventors, Messrs. Bradley and Lovejoy, are given in the *Electrical World and Engineer* (N.Y.) for August 2 last. A cylindrical metal box is provided on its inner surface with six upright rows of fixed contacts, there being twenty-three contacts in each row. Each contact is connected through an inductance to the positive pole of a dynamo generating direct current at a pressure of 10,000 volts. A similar set of contacts is mounted on an inner rotating cylinder connected to the negative pole of the generator. As the inner cylinder rotates, the negative contacts come up to the positive and an arc strikes across; this is gradually drawn out and finally extinguished as the negative contact moves past, and away from, the positive. The action may be likened to the rotation of the cylinder in a musical box. Air circulates amongst the arcs, and is drawn off containing about 2½ per cent.

of oxides of nitrogen and led to absorbing towers. The air is circulated at the rate of about 5 cubic feet per contact per hour, and the inner cylinder rotates at the rate of 500 revolutions per minute, thus forming more than 400,000 arcs per minute. Sufficient data are not given to enable a calculation of the efficiency of the arrangement to be made. It will be remembered, however, that the result of Lord Rayleigh's experiment showed that, given cheap power, nitrates could be made by this process at less than the present cost.

THE geology of western Rajputana forms the subject of an essay by Mr. Tom D. La Touche (*Mem.* Geol. Survey India, vol. xxxv. pt. i. 1902). The country is for the most part a vast sandy plain diversified only by sand hills and by isolated knolls and groups of hills composed almost wholly of crystalline rocks. Except when rain is falling, no running water is to be seen, and the principal agents of erosion are the intense heat of the sun, or rather the great alternations of temperature that act on the superficial layers of rock, and the violent winds aided by the sand they bear with them. Deflation, or the action of sand-laden wind, is illustrated in many curious features, notably in certain scarped outliers of horizontal beds of sandstone which appear like pyramids in the plain. Some of these known as *zeugen* or "witnesses" are figured. The crystalline rocks exposed comprise schists and quartzite, granites, rhyolites and basic dykes. The sedimentary rocks include the Vindhyan, Talchir boulder-beds, Cretaceous (?) Sandstone, Nummulitic Limestone, and recent accumulations.

IN a recent issue of the *Journal* of the Asiatic Society of Bengal, Major J. Manners-Smith records the existence of hybrids between the common wolf and domesticated dogs in the Gilgit district.

IN the October number of the *Entomologist's Monthly Magazine*, Mr. Charles Rothschild describes two new British species of fleas, the one infesting the moorhen and the other various small mammals.

MR. W. L. DISTANT, in a recent issue of the *Annals* of the South African Museum (vol. ii. pt. ix. art. xii.), publishes a series of notes on the bugs of the country, with descriptions of new species.

IN a paper on the fishes of Mexico, published by the Field Columbian Museum (zool. series, vol. iii. No. 6), Mr. S. E. Meek figures a female of a viviparous species of Goodea in which the ovary is absolutely crammed with young.

A RECENT supplement to the *Tropical Agriculturist* (Colombo) contains the text of a preliminary report by Prof. Herdman, F.R.S., on the pearl fisheries of Ceylon. The report may, we understand, be seen by those interested at the Commercial Intelligence Branch of the Board of Trade, 50 Parliament Street, S.W.

IN the *Proceedings* of the U.S. Museum, Messrs. Jordan and Fowler continue their survey of the fishes of Japan, the latest fasciculus dealing with the trigger-fishes, file-fishes and trunk-fishes. Excellent figures are given of some of these strange fishes, one of which is made the type of a new species and genus.

THE effect of wind on the migration of birds, as exemplified by the case of hawks, forms the subject of an interesting article by Mr. C. C. Trowbridge in the September issue of the *American Naturalist*. It is inferred that the migratory movements of hawks are very largely affected by wind, an adverse wind retarding, if not completely arresting them. Several other conditions of the atmosphere which affect the migration are mentioned by the author.

IN the October number of the *Journal of Conchology*, Mr. R. Welch describes and figures a number of "sports" of the common black-lipped snail (*Helix nemoralis*), showing the spiral more or less elongated above the normal. It appears that enormous numbers of these snails are collected by the peasant women in a certain district of Donegal for the purpose of making necklaces of the shells. Among this number a small percentage of reversed specimens and others with abnormally tall spires are met with and picked out for special sale. In one of the figured specimens the spiral is so elongated as to recall a Scalaria.

IN the August issue of the *Biological Bulletin*, Mr. H. F. Perkins describes a remarkable degeneration-process observed in larval cœlenterates of the genus Gonionema. After mentioning the manner in which the larvæ disintegrate, the author observes that "the repeated fission of the individuals resulted in such diminution of the size of the pieces which came from the original individuals that after a time it was impossible to distinguish the bits of living matter from the other particles lying about on the bottom. But during the entire time in which it was possible to recognise the pieces of disintegrating larvæ, the sum total of this substance did not seem to be at all diminishing. It is impossible to assign any satisfactory explanation to the phenomena, but it is not unlikely that the condition of the water in this particular aquarium was peculiar."

THE affinities of that remarkable group of worm-like creatures known as Solenogastræ and their relationship to the Mollusca form the subject of a long article by Herr J. Thiele in the *Zeitschrift für wissenschaftliche Zoologie* (vol. lxxii. pts. ii. and iii). There are two families of these organisms, the one typified by Neomenia and the other by Chætoderma. Very generally the group is classed among the molluscs with the chitons; the author is, however, of opinion that the Solenogastræ are really worms allied to the thread-worms (as represented by the Gordiidæ) and annelids, but, in the relation of the heart to the uterus, as well as in the possession of a rudimentary tongue, or radula, approximating to the molluscs, and more especially to the chitons. If this view be correct, the Mollusca are descended from worms, the chitons representing the transitional type.

As the result of a considerable number of experiments, Dr. Margaret C. Ferguson finds that the most effectual plan for starting the germination of spores of *Agaricus campestris* is to include in the culture either some of the mycelium of this plant or else some spores which have already been induced to germinate. An account of the various methods devised to bring about the germination of spores of this and various basidiomycetous fungi is published as a *Bulletin* of the U.S.A. Department of Agriculture. An extremely useful historical summary of similar experiments is given at the end of the paper.

THE latest parts of Engler's "Botanisches Jahrbuch" contain a monograph of the Berberidaceæ and Podophyllaceæ, in which the writer, Dr. G. Tischler, proposes a separate order for Podophyllum and Diphylleia. Herr Breyer finds that a comparative study of certain of the Anonaceæ bears out the latest division of that order by Engler and Diels into two suborders only, the Uvarioideæ and the Eupomatioideæ. An article, "Der Wind als pflanzengeographischer Factor," by Dr. Warming, is mainly a polemic against Prof. Hansen's book dealing with the East Friesian Islands. Another proposal to deal with the present confused terminology of phytogeography originates from America, and a system of nomenclature is suggested by Mr. F. E. Clements, of Nebraska.

MATTHEW ARNOLD'S well-known work on "Literature and Dogma," which, as its subtitle explains, is "An Essay towards a better Apprehension of the Bible,' has been issued for the

Rationalist Press Association, Ltd., in paper covers at sixpence, by Messrs. Watts and Co.

A NEW medical and scientific circulating library has been opened by Mr. T. H. Prince, who was for many years with Mr. H. K. Lewis, and has just started as a medical and scientific bookseller at Praed Street, Paddington. It is promised that all standard works in the various branches of science will be available to subscribers.

WE have received the concluding part of the *Boletim Mensal* of the Observatory of Rio de Janeiro for the year 1901. In addition to the meteorological observations taken eight times daily at that observatory, the *Bulletin* contains monthly and yearly results for various parts of Brazil, and a valuable summary for twenty years (ending March, 1901) for Bahia, from observations made by Dr. Guimarães.

SEVERAL new forms of apparatus for the physical laboratory have lately been produced by Messrs. W. G. Pye and Co., Cambridge. Among the instruments are a table cathetometer and a reading microscope, constructed on the geometric slide principle, an improved pattern storage cell, five hundred of which have been in use at the Cavendish Laboratory for several months and have proved "very convenient and thoroughly satisfactory," and sets of patent resistance coils, in which the coils themselves take the place of the usual plugs and can be easily removed to show the wire and method of construction.

A NOTEWORTHY paper on the decomposition of urea is contributed by Mr. C. E. Fawsitt to the fifth number of the *Zeitschrift für physikalische Chemie*, vol. xli. When a pure aqueous solution of urea is heated at 100° C. for a considerable time, the urea is completely transformed into ammonium carbonate. This decomposition takes place also under the influence or acids and bases, the velocity under these circumstances being much greater. If strongly alkaline solutions are excepted, the decomposition takes place in all cases according to the simple equation for a unimolecular reaction, a result which does not accord with the ordinary method of representing the reaction. The author finds that the facts can only be satisfactorily explained by assuming that the urea is in the first place transformed into ammonium cyanate and that a state of equilibrium is set up between these two substances. The cyanate, however, is gradually decomposed with the formation of ammonium carbonate, the equilibrium being thus disturbed, and a further quantity of urea undergoes transformation into the cyanate. This decomposition of ammonium cyanate into ammonium carbonate takes place very quickly under the influence of acids. A large amount of experimental evidence is found to support the theory advanced, and the author concludes that urea is not directly attacked either by water, acids or moderately concentrated alkalis. Concentrated solutions of the alkalis have probably however a direct saponifying action upon the urea, in addition to the indirect action described.

AN investigation of the rate of bromination of carbon compounds by L. Bruner, which will be of considerable interest to organic chemists, is published in the current number of the *Zeitschrift fur physikalische Chemie*. The catalytic action of iodine on the bromination of benzene has been carefully studied in a quantitative manner, and it is shown that this action is very probably due to the formation of iodine monobromide, which by its dissociation gives rise to free bromine atoms. These free bromine atoms are the active agents in the bromination process, and the catalytic influence of the iodine is due to the much greater dissociation of the iodine bromide as compared with that of bromine itself. The author shows that the substitution of bromine is a quadrimolecular reaction taking place according to the equation

$$C_6H_6 + 4Br = C_6H_5Br + HBr_3 \rightleftharpoons Br_2.$$

The action of other carriers has also been investigated, the most active in the case of the bromination of benzene and bromobenzene being aluminium bromide. This compound has, however, no influence on the bromination of nitrobenzene. From the concentrated nitrobenzene solution, a compound of the formula $AlBr_3 \cdot 2C_6H_5NO_2$ has been crystallised out, a fact of some interest in view of Gustavson's theory of the mode of action of $AlBr_3$ in the bromination of benzene, toluene and other compounds. The author has finally investigated the relative velocities of some so-called instantaneous reactions. It is found that the bromination of aniline takes place more rapidly than that of phenol, and that the velocity of the latter reaction is about one-fifth of that at which iodine is separated by bromine from potassium iodide solution.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mrs. Chas. Lisle Hacket; two Mozambique Monkeys (*Cercopithecus pygerythrus*) from East Africa, presented respectively by Mr. J. M. Creasey and Mrs. G. Ord; a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mrs. Murray Simpson; a Gannet (*Sula bassana*) from Scotland, presented by Lord Ribblesdale; six Carolina Anolis (*Anolis carolinensis*) from Florida, two Tarantula Spiders, from Arizona, presented by Miss Ilda Orme; two Entellus Monkeys (*Semnopithecus entellus*), two Sambur Deer (*Cervus aristotelis*), two Nylghaies (*Boselaphus tragocamelus*), two Tigers (*Felis tigris*), two Gadwells (*Chaulelasmus streperus*), an Indian Adjutant (*Leptoptilus argala*) from India, two Nutmeg Fruit Pigeons (*Myristicivora bicolor*) from Moluccas, received in exchange; eight Saddle-backed Tortoises (*Testudo ephippium*), two Thin-shelled Tortoises (*Testudo microphys*), twenty-four South Albemarle Tortoises (*Testudo vicina*), one —— Tortoise (*Testudo* ——), seven —— Iguanas (*Conolophus subcristatus*) from the Galapagos, four Indian Porphyrios (*Porphyrio calvus*) from Eastern Asia, a Brindled Gnu (*Connochaetes taurina*) from South Africa, deposited.

OUR ASTRONOMICAL COLUMN.

A NEW TRANSITING DEVICE.—An article by Mr. M. B. Snyder, of the Philadelphia Observatory, in *Popular Astronomy*, No. 97, discusses a new device for transiting stars, in which the micrometer thread is moved, with a regular speed, across the field by means of an electric motor.

The fundamental idea of getting rid of the personal equation in transit observations by using mechanical transiters was first suggested by Braun in 1865 and since then has been persistently developed by Repsold. After discussing the various methods suggested by these and other inventors, Mr. Snyder gives some details of his own device, although full details are withheld for a future communication when circumstances have permitted of more time being spent on the subject.

In Mr. Snyder's instrument, the micrometer screw, and thereby the micrometer thread, is driven across the field of the instrument by an electric motor, at a speed depending on the declination of the object observed, whilst at the same time the observer, by using a secondary adjustment, keeps the star image accurately bisected, and the various positions of the thread are automatically recorded, by means of an ordinary chronograph, at the end of each revolution of the screw. Then at the moment of meridian passage an automatic electrical arrangement records the instant of transit. The micrometer in its fundamentals is of the ordinary type, and is at present attached to the 4-inch meridian circle of the Philadelphia Observatory; it is so arranged that, with the motor driving regularly, visual observations may be made, and recorded by any one of the usual methods, synchronously, thus forming a ready means of determining the personal equations existing between the various individuals of any group of observers.

THE SEARCH FOR A PLANET BEYOND NEPTUNE.—Herr T. Grigull, of Münster, Germany, describes in the October number of the *Bulletin de la Société Astronomique de France* his new contribution to the research which has for its object the discovery of another planet, beyond the orbit of Neptune.

In a previous paper (*Bulletin*, January, 1902, p. 31), Herr Grigull explained the hypothesis on which his calculations are based, and the elements of the hypothetical planet as deduced from the observations of the aphelia of three comets. In the present contribution, the elements given below have been calculated from the observed aphelia of twenty comets which appeared, and were observed and recorded, between the years 1490 and 1898. After giving due weight to the various cometary observations, the author has calculated these elements for the possibly existing planet :—

Epoch 1902.

$$\lambda = 357^{\circ}\cdot54 \pm 1^{\circ}\cdot867$$
$$\text{Dist. from sun} = 50\cdot61 \text{ R.}$$
$$\text{Time of revolution} = 360 \text{ years.}$$
$$\Omega = 90^{\circ} \text{ (???).}$$
$$\omega = ?.$$

A NEW MINOR PLANET.—In No. 3819 of the *Astronomische Nachrichten*, Prof. Max Wolf announces, along with other minor planetary observations, the discovery of another new minor planet, 1902 T.

COMET 1902 *b*.—A number of observations of this comet have been made.

A photograph taken on September 27 by Prof. Kononowitsch, Odessa, with three hours' exposure, shows a straight double tail extending in a southerly direction to a distance of 3°.

Prof. Nijland has published, in the *Astronomische Nachrichten* (No. 3817), a further ephemeris, from which the following extract is taken :—

1902.	app. α. h. m. s.	app. δ. ° ′	Brightness.
Oct. 16 ...	18 16 24 ...	+16 30·5	
17 ...	9 55 ...	14 9·1	
18 ...	4 7 ...	11 58·9 ...	13·0
19 ...	17 58 52 ...	9 59·1	
20 ...	54 6 ...	8 8·9	
21 ...	49 43 ...	6 27·3	
22 ...	45 41 ...	4 53·6 ...	10·9
23 ...	17 41 56 ...	+3 26·9	

The brightness of the comet on September 6 is taken as unity, and it was then estimated at 7·5m.

THE BRITISH ASSOCIATION AT BELFAST.

SECTION A.

SUBSECTION OF ASTRONOMY AND COSMICAL PHYSICS.

OPENING ADDRESS BY ARTHUR SCHUSTER, F.R.S., F.R.A.S., CHAIRMAN OF SUBSECTION.

OUR proceedings to-day constitute an innovation and require a few words of explanation. When, a few years ago, some astronomers felt that our Association bestowed an insufficient share of attention on their subject, an easy remedy suggested itself in the formation of a special subsection devoted to that subject. Such a subsection was accordingly organised at Bradford and Glasgow, but for reasons, which are perhaps not altogether to be regretted, the experiment was only partially successful. In the meantime the work of Section A became heavier and heavier, and, as it seemed necessary to find some way of relieving its meetings, it was decided to hand over to the already established subsection of Astronomy other subjects, such as Meteorology, Terrestrial Magnetism, Seismology, and, in fact, anything that the majority of physicists is only too glad to ignore.

When the Council of the British Association asked me to act as President of such an enlarged subsection, I was very doubtful whether I ought to accept the honour. In the first place, I felt incompetent, owing to my almost complete ignorance of most branches of astronomy, and in the second place I do not approve of the formation of subsections dealing with important branches of Physics. If I eventually consented, it was partly because I lacked the strength of mind to refuse an honour of this kind, but partly because I was glad to have an opportunity of raising the whole question of the organisation of our meetings. The ground for such a discussion has, however, to a great extent disappeared, because, when the Organising Committee of Section A met in the spring, there appeared amongst those present a sudden revival of interest in the subjects assigned to the subsection and it was decided that the main section should not meet at all to-day so as to allow its members to help us in our discussions. The parent section has, therefore, voluntarily submitted itself to absorption by its neglected offspring, which now has to show that Cosmical Physics obeys the laws of Terrestrial Physics and that good absorbers are also good radiators.

Gratifying as this reunion must be to us, it fails to realise one of the original objects for which we have been called into existence, because instead of lightening your work it has added to it by imposing upon you the burden of having to listen to a second Presidential Address. I will try to make this additional burden as light as possible by concentrating my general remarks into a few sentences and then introducing the business of the section by means of a contribution to its scientific work, which I otherwise should have made in the ordinary course of the meeting.

To make our meeting as fruitful as possible, we should make the fullest use of the opportunities it gives us of personal contact and interchange of ideas. This is not accomplished by dividing into separate camps as soon as we have come together, but rather by finding some common ground for our debates. We should not try to minister to the separate needs of the specialist in electricity, or in meteorology or in astronomy, but should impress upon each of these specialists that they must bring before us the results of their investigations in so far as they bear on the more general questions in which we all are, or ought to be, interested. If it is necessary to lighten the work of the section this should be done by excluding all papers which are of interest only to specialists, or by establishing subsections for such papers. Let us divide—if divide we must—according to the character of the contribution, rather than according to the subject it happens to deal with. The difficult and, perhaps, unpopular censorship which such a course would involve would probably be temporary only, as the character of the papers which are desired for the main section would soon become known, and the increased attraction and usefulness of our discussions would, I am convinced, in a few years compensate for the initial trouble. We all require, occasionally, to be reminded that the detail work which is necessary, and on which most of us are engaged, is only of importance or interest if it helps us forward towards the solution of the great problems of Nature.

Addressing myself more particularly to Astronomers, I should like to say that we shall always welcome them as members of Section A, and that the benefit we shall derive from their contributions will be great in proportion as they will consider themselves to be citizens of the general empire of that section rather than inhabitants of an independently governed State.

There is one minor reform, or perhaps I ought to call it a protest against one of the traditions of the Association, which I feel called upon to urge on you. Discussion is our principal aim, and we are always trying to find suitable subjects for discussion ; yet we are prevented by the rules of the Association from discussing the Presidential address and the reports of Committees. Those who framed such a rule must have had some unfortunate idea that the dignity of the chair might be endangered if some criticism happened to be expressed in the discussion of the Chairman's address, or that the value of the report of a Committee might be endangered by some adverse comment coming from outside. But it seems to me that a scientific society or association, and especially one framed on a democratic constitution, ought not to take such a narrow and unscientific view. I can remember several Presidential addresses which might, and probably would, have given rise to most instructive debates had the rule not existed. Reports of Committees if not suitable for discussion should not be read at all ; but if read they should be open to discussion.

I hope that to-day you will not feel yourself bound by ancient custom, but in order that, at any rate, the more scientific portion of my contribution to our proceedings should not be stained by the suspicion of immaculate conception, I will now ask the duly-constituted President of our section to take his proper place.

The question I wish to bring to your notice to-day is an old one : if two events happen simultaneously or one follows the

other at a short interval of time, does this give us any reason to suppose that these two events are connected with each other, both being due to the same cause, or one being the cause of the other? Everyone admits that the simple concurrence of events proves nothing, but if the same combination recurs sufficiently often we may reasonably conclude that there is a real connection. The question to be decided in each case is what is "sufficient" and what is "reasonable." Here we must draw a distinction between experiment and observation. We often think it sufficient to repeat an experiment three or four times to establish a certain fact, but with meteorological observations the case is different, and it would, *e.g.*, prove very little if on four successive full moons the rainfall had been exceptionally high or exceptionally low. The cause of the difference lies in the fact that in an experiment we can control to a great extent all the circumstances on which the result depends, and we are generally right in assuming that an experiment which gives a certain result on three successive days will do so always. But even this sometimes depends on the fact that the apparatus is not disturbed, and that the housemaid has not come in to dust the room. Here lies the difference. What is possible in a laboratory, though perhaps difficult, is not possible in the upper regions of the atmosphere, where some unseen hand has not made a clean sweep of some important condition.

When we cannot control accessory circumstances we must eliminate them by properly combining the observations and increasing their number. The advantage does not lie altogether on the side of experiment, because the very identity of condition under which the experiment is performed gives rise to systematic errors, which Nature eliminates for us in the observational sciences. In the latter also the great variety in the combinations which offer themselves allow us to apply the calculus of probability, so that in any conclusion we draw we can form an idea of the chance that we are wrong. Astronomers are in the habit of giving the value the "probable error" in the publication of their observations. Meteorologists have not adopted this custom, and yet their science lends itself more readily than any other to the evaluation of the deviations from the mean result, on which the determination of the probable error depends. We look forward to the time when weather forecasts will be accompanied by a statement of the odds that the prediction will be fulfilled.

The calculation of the probability that any relationship we may trace in different phenomena indicates a real connection seems to me to be vital to the true progress of Meteorology, and although I have on previous occasions (Cambridge *Phil. Trans.*, vol. xviii. p. 107) already drawn attention to this matter I should like once more to lay stress on it.

The particular case I wish to discuss (though the methods are not restricted to this case) is that in which one of the two series of events between which relationship is to be established has a definite period, and it is desired to investigate the evidence of an equal period in the other series.

Connections between the moon and earthquakes, or between sunspots and rainfall if proved to exist, would form examples of such relationships. The question to be decided in these cases would be, is there a lunar period of earthquakes, or an eleven years' sunspot period of rainfall.

Everyone familiar with Fourier's analysis knows that there is a lunar or sunspot, or any other period in any set of events from volcanic eruptions down to the birth-rate of mice; what we want to find out is whether the periodicity indicates a real connection or not. Let us put the problem into its simplest form. Take n balls, and by some mechanism allow them to drop so that each falls into one of m compartments. If finally they are equally distributed each compartment would hold n/m balls. If this is not the case we may wish to find out whether the observed inequality is sufficient to indicate any preference for one compartment or how far it is compatible with equality of chance for each. If we were able to repeat the experiment as often as we like we should have no difficulty in deciding between the two cases, because in the long run the average number received by each compartment would indicate more and more closely the extent of bias which the dropping mechanism might possess. But we are supposed to be confined to a single trial, and draw our conclusions as far as we can from it.

It would be easy to calculate the probability that the number of balls in any one compartment should exceed a given number, but in order to make this investigation applicable to the general problem of periodicities we must proceed in a different manner. If the compartments are numbered, it does not matter in which order, and a curve be drawn in the usual manner representing the connection between the compartments and the number of balls in each, we may, by Fourier's analysis, express the result by means of periodic functions. The amplitude of each period can be shown *on the average* to be $\frac{1}{m}\sqrt{\pi n}$. It is often more convenient to take the square of the amplitude—call it the intensity—as a test, and we may then say that the "expectancy" of the intensity is $4n/m^2$. The probability that the intensity of any period should be k times its average or expectancy is e^{-k}. We may apply this result to test the reality of a number of coincidences in periods which have been suspected. A lunar effect on earthquakes is in itself not improbable, as we may imagine the final catastrophe to be started by some tidal deformation of the earth's crust. The occurrence of more than 7000 earthquakes in Japan has been carefully tabulated by Mr. Knott according to lunar hours, who found the Fourier coefficient for the lunar day and its three first sub-multiples to be 10·3, 17·9, 10·9, 3·97; the expectancy on the hypothesis of chance distribution for these coefficients I find to be 19·3, 15·7, 10·6, 5·02. The comparison of their numbers disproves the supposed connection; on the other hand, the investigations of Mr. Davison on solar influence have led to a result much in favour of such influence, the amplitude found being in one series of observations equal to five times, and in the other to fifteen times the expectancy. The probability that so large an amplitude is due to accident in the first case is one in 300 millions, and in the second the probability of chance coincidence would be represented by a fraction, which would contain a number of over 70 figures in the denominator. We may, therefore, take it to be established that the frequency of earthquakes depends on the time of year, being greater in winter than in summer. With not quite the same amount of certainty, but still with considerable probability, it has also been shown that earthquake shocks show a preference for the hours between 9 a.m. and noon.

A great advantage of the scientific treatment of periodical occurrences lies in the fact that we may determine *a priori* how many events it is necessary to take into account in order to prove an effect of given magnitude. Let us agree, for instance, that we are satisfied with a probability of a million to one as giving us reasonable security against a chance coincidence. Let there be a periodic effect of such a nature that the ratio of the occurrence at the time of maximum to that at the time of minimum shall on the average be as $1+\lambda$ to $1-\lambda$, then the number of observations necessary to establish such an effect is given by the equation $n = 200/\lambda^2$. If there are 2 per cent. more occurrences at the time of maximum than at the time of minimum $\lambda = \cdot 01$, and n is equal to two million. If the effect is 5 per cent., the number of events required to establish it is 80,000.

To illustrate these results further, I take as a second example a suggested connection between the occurrence of thunderstorms and the relative position of sun and moon. Among the various statistical investigations which have been made on this point, that of Mr. MacDowall lends itself most easily to treatment by the theory of probability. One hundred and eighty-two thunderstorms observed at Greenwich during a period of fourteen years have been plotted by Mr. MacDowall as distributed through the different phases of the moon, and seem to show a striking connection. I have calculated the principal Fourier coefficient from the data supplied, and find that it indicates a lunar periodicity giving for the ratio of the number of thunderstorms near new moon to that near full moon the fraction 8·17 to 4·83.

This apparently indicates a very strong effect, but the inequality is only twice as great as that we should expect if thunderstorms were distributed quite at random over the month, and the probability of a true connection is only about 20 to 1. No decisive conclusions can be founded on this, the number of thunderstorms taken into account being far too small. We might dismiss as equally inconclusive most of the other researches published on the subject were it not for a remarkable agreement among them, that a larger number of storms occur near new moon than near full moon.

I have put together in the following table the results of all investigations that are known to me; following the example of Koeppen, I have placed in parallel columns the number of thunderstorms which have occurred during the fortnight including new moon, and the first quarter and the fortnight including the other two phases.

Place of observation and author.	Time of observations.	Percentage of thunderstorms during the fortnight including: New moon and first quarter.	Full moon and last quarter.

It will be seen that out of fourteen comparisons, thirteen show higher numbers in the first column, there being also, except in two cases, a general agreement as regards the magnitude of the effect. Two of the stations given in the table, Göttingen and Gotha, are perhaps geographically too near together to be treated as independent stations, and we may, therefore, say that there are thirteen cases of agreement, against which there is only one published investigation (Schiaparelli) in which the maximum effect is near full moon.

The probability that out of thirteen cases in which there are two alternatives, selected at random, twelve should agree and one disagree is one in twelve hundred. If the details of the investigations summarised in the above table are examined, considerable differences are found, the maximum taking place sometimes before new moon and sometimes a week later. There is, however, evidently sufficient *prima facie* evidence to render an exhaustive investigation desirable. The most remarkable of all coincidences between thunderstorms and the position of the moon remains to be quoted. A. Richter has arranged the thunderstorms observed at Glatz, in Silesia, according to lunar hours, and finds that in each of seven successive years the maximum takes place within the four hours beginning with upper culmination. If this coincidence is a freak of chance, the probability of its recurrence is only one in three hundred thousand. The seven years which were subjected to calculation ended in 1884. What has happened since? Eighteen years have now elapsed, and a further discussion with increased material would have definitely settled the question, but nothing has been done, or, at any rate, published. To me it seems quite unintelligible how a matter of this kind can be left in this unsatisfactory state. Meteorological observations have been allowed to accumulate for years, one might be tempted to say for centuries, yet when a question of extraordinary interest arises we are obliged to remain satisfied with partial discussion of insufficient data.

The cases I have so far discussed were confined to periodical recurrences of single detached and independent events, the condition, under which the mathematical results hold true, being that every event is entirely independent of every other one. But many phenomena, which it is desirable to examine for periodic regularities, are not of this nature. The barometric pressure, for instance, varies from day to day in such a manner that the deviations from the mean on successive days are not independent. If the barometer on any particular day stands half an inch above its average it is much more likely that on the following day it should deviate from the mean by the same amount in the same direction than that it should stand half an inch below its mean value. This renders it necessary to modify the method of reduction, but the theory of probability is still capable of supplying a safe and certain test of the reality of any supposed periodic influence. I can only briefly indicate the mathematical theorem on which the test is founded. The calculation of Fourier's coefficients depends on the calculation of a certain time integral. This time integral will for truly homogeneous periodicities oscillate about a mean value, which increases proportionately to the interval, while for variations showing no preference for any given period, the increase is only proportional to the square root of the time.

Investigations of periodicities are much facilitated by a certain preliminary treatment of the observations suggested by an optical analogy. The curve, which marks the changes of such variables as the barometric pressure, presents characteristics similar to those marking the curve of disturbance along a ray of white light. The exact outline of the luminous disturbance is unknown to us, but we obtain valuable information from its prismatic analysis, which enables us to draw curves connecting the period and intensity of vibration. For luminous solids we thus get a curve of zero intensity for infinitely short or infinitely long radiations, but having a maximum for a period depending on temperature. Gases, which show preference for more or less homogeneous vibrations, will give a serrated outline of the intensity curve.

I believe meteorologists would find it useful to draw similar curves connecting intensity and period for all variations which vary round a mean value such as barometric, thermometric or magnetic variations. These curves will, I believe, in all cases add much to our knowledge; but they are absolutely essential if systematic searches are to be made for homogeneous periods. The absence of any knowledge of the intensity of periodic variation renders it, *e.g.*, impossible to judge of the reality of the lunar effect which Eckholm and Arrhenius believe to have traced in the variations of electric potential on the surface of the earth. The problem of separating any homogeneous variation, such as might be due to lunar or sunspot effects, is identical with the problem of separating the bright lines of the chromosphere from the continuous overlapping spectrum of the sun. This separation is accomplished by applying spectroscopes of great resolving powers. In the Fourier analysis, resolving power corresponds to the interval of time which is taken into account, hence to discover periodicities of small amplitude we must extend the time interval of the observations.

I believe that the curve which connects the intensity with the period will play an important *rôle* in meteorology. It is a curve which ought to have a name, and for want of a better one I have suggested that of periodograph. To take once more barometric variations as an example, it is easy to see that just as in the case of white light the periodograph would be zero for very short, and probably also for very long, periods. There must be some period for which intensity of variation is a maximum. Where is that maximum? And does it vary according to locality? The answer to these questions might give us valuable information on the difference of climate. Once the periodograph has been obtained, the question of testing the reality of any special periodicity is an extremely simple one. If h be the height of the periodograph, the probability that, during the time interval chosen, the square of the Fourier coefficient should exceed kh is e^{-k}. If we wish this quantity to be less than a million, k must be about 11; so that in order to be reasonably certain that any periodicity indicates the existence of a truly homogeneous variation, the square of the Fourier coefficient found should not be less than 11 times the corresponding ordinate of a periodograph

I have calculated in detail the periodograph of the changes of magnetic declination at Greenwich, taking as basis the observations published for the 25 years 1871–95. It was not, perhaps, a very good example to choose, on account of the complications introduced by the secular variation, but my object was to test the very persistent assertions that have been made as to the reality of periodic changes of 26 days or thereabouts. The first suggestion of such a period came from Hornstein, of Prague, who ascribed the cause of the period to the time of revolution of the sun round its axis. He only discussed the records for one year's observations, but the evidence he offered was sufficient to impress Clerk Maxwell with its genuineness. Since Hornstein's first attempts, a great many rough and some very elaborate efforts have been made by himself and others to prove a similar period in various meteorological variations. The period found by different computors differed, but there is a good deal of latitude allowed if the rotation of the sun really has an effect on terrestrial phenomena, because the angular velocity of the visible solar surface varies with the latitude. Hornstein himself and some of his followers deduced a period

not differing much from 26 days, while Prof. Frank Bigelow, using a large quantity of material, finds 26·68 days, and Eckholm and Arrhenius return to 26 days, or, as they put it more accurately, to 25·929 days. The two latter investigators do not, however, adopt the idea that this periodicity is due to the rotation of the sun. None of these periods can stand the test of accurate investigation.

As the result of my calculations, I can definitely state that the magnetic declination at Greenwich shows no period between 25·5 and 27·5 days having an amplitude as great as 6″ of arc. The influence of solar rotation on magnetic variation may therefore be considered to be definitely disproved.

The intensity of the periodograph increases rapidly with the period, and minute variations are, therefore, more easily detected in short than in longer periods. Six seconds of arc forms about the limit of amplitude, which can be detected in 25 years of observations, when the period is about 26 days; and from what has been said above, the amplitude which can be detected will be seen to vary inversely with the square root of the time interval. For periods of about 14 days, an amplitude of 3″ of arc is still distinguishable with the material I have used; and such an amplitude is actually found for a period which has half the synodic month as its time. The chance that this apparent variation is due to an accidental coincidence is one in two thousand; and I cannot, therefore, assert its definite existence beyond all possibility of cavil. But it is surely significant that of all the periods possible between 12·3 and 13·7 days, that gives the highest amplitude which coincides with half the synodic revolution of the moon. That it is at all possible to detect variations of 3″ of arc in the observations which are taken to 6″, with a probability of error of only one in two thousand, is, I think, a proof of the value of the method and the carefulness of the observations. The periodograph has another valuable use. It not only gives us the time necessary to establish true periodicities of given amplitude, but it also gives us an outside limit of the time beyond which an accumulation of material is of no further advantage. That limit is reached when the time is sufficient to discover the smallest amplitude which the instruments, owing to their imperfections, allow us to detect.

I am only concerned to-day with a purely statistical inquiry, and not with the explanation of any suggested relationship. To prevent misunderstandings, however, I may state that I consider the possibility of a direct magnetic or electric action of the moon excluded; as regards the latter, the diurnal variations of electric potential would be so much affected by a lunar electrification sufficiently strong to influence the outbreak of thunderstorms that it could not have escaped discovery. We must not, however, be dogmatic in asserting the impossibility of indirect action. The unexpected discovery of radio-activity has opened out an entirely new field, and we cannot dismiss without renewed careful inquiry the evidence of lunar action which I have given. Its reality can be decided by observation only. No—not by observation only—but by observation supplemented by intelligent discussion; and this brings me to my concluding appeal, which I wish to urge upon you with all the legitimate weight of strong conviction and all the illegitimate influence of presidential infallibility.

The subjects with which our subsection is concerned deal with facts which are revealed to us by observation more frequently than by experiment. There is in consequence a very real danger that the importance of observation misleads us into mistaking the means for the end, as if observation alone could add anything to our knowledge. Observation is like the food supplied to the brain, and knowledge only comes through the digestion of the food. An observation made for its own sake and not for some definite scientific object is a useless observation. Science is not a museum for the storage of disconnected facts and the amusement of the collecting enthusiast. I dislike the name "observatory" for the astronomical workshop, for the same reason that I should dislike my body to be called a food receptacle. Your observing dome would be useless without your computing room and your study. What you want is an Astronomical Laboratory, a Meteorological or Magnetic Laboratory, attaching to the word "laboratory" its true meaning, which is a workshop in which eyes and hands and brains unite in producing a combined result.

The problems which confront the astronomer being more definite than those of Meteorology, Astronomy has grown under the stimulus of a healthy tradition. Hence it is generally recognised, at any rate in the principal observatories, that the advance of knowledge is the chief function of the observer. Nevertheless, the President of the Astronomical Department of Section A last year (Prof. H. H. Turner) has found it necessary, in his admirable address, to warn against the danger there is that the astronomer should allow himself to be swallowed up in a routine work and mere drudgery. The descent is easy: You begin by being a scientific man, you become an observer, then a machine, and finally—if all goes well—you design a new eyepiece.

If such a danger exists in Astronomy, what shall we say about Meteorology? That science is bred on routine, and drudgery is often its highest ambition. The heavens may fall in, but the wet bulb must be read. Observations are essential, but though you may never be able to observe enough, I think you can observe too much. I do not forget the advances which Meteorology has made in recent years, but if you look at these advances, I think you will find that most of them do not depend on the accumulation of a vast quantity of material. The progress in some cases has come through theory, as in the applications of Thermodynamics or through special experiments as by kite and balloon observations, and when it has come through the ordinary channels of observation, only a comparatively short period of time has been ultilised. It would not be a great exaggeration to say that Meteorology has advanced in spite of the observations and not because of them.

What can we do to mend matters? If we wish to prepare the way for the gradual substitution of a better system, we should have some one responsible for the continuation of the present one. For this purpose it should be recognised that the head of the Meteorological Office is something more than a Secretary to a Board of Directors; also that he is appointed to conduct Meteorological research and not to sign weather forecasts. The endowment of Meteorology should mean a good deal more than the endowment of the Telegraph Office which transmits the observations. Terrestrial Magnetism and Atmospheric Electricity are looked after at present by institutions already overworked in other directions and should be handed over to an enlarged Department of Meteorology. Seismology in this country now depends on the private enterprise and enthusiasm of a single man, and as long as Prof. Milne is willing to continue his work, we cannot do better than leave it with him, but some permanent provision will ultimately have to be made.

An improved organisation such as I have sketched out would do good, but could only very slowly overcome the accumulated inertia of ages. I should prefer a more radical treatment. Organisation is good, but sometimes disorganisation is better.

Most earnestly do I believe that the subjects of meteorology and terrestrial magnetism, and possibly also of atmospheric electricity, could be most quickly advanced at the present moment if all observations were stopped for five years, and all the energy of all observers and computors concentrated on the discussion of the results obtained and the preparation of an improved scheme of observation for the future. When we have made up our minds what to do with the observations, when we have actually done it; when we know where our present instruments require refining or supplementing, and especially when we have found out whether we have not spent much time and trouble on unnecessary detail, then the time will have arrived for us to draw up an economical, sufficient and efficient scheme of observations. At present we are disinclined to discontinue observations, though recognised as useless, for fear of causing a break. We make ourselves slaves to so-called "continuity," which is important, but, may be, and I believe is being, too dearly purchased.

There are no doubt some, though probably not very many, observations which it is necessary to carry on continuously over long periods of time. But at present we are groping in the dark, and go on observing everything, and always in the hope that some time the observations might prove useful. Our whole point of view in this respect wants altering. We should fix on our problem first and then provide the observations which are necessary for the solution of the problem. Let us restrict, in the first instance, the secular observations to the smallest number, and concentrate our attention, for short periods of time, on some special question. Let us have, for instance, two or three years of thunderstorm observations, all countries joining in concentrating their energies to the elucidation of all the various features of their phenomena. When that is accomplished, it will probably be found that thunderstorms may be left to shift for themselves for a while, and attention might be

directed to some other matter. The whole question of lunar influence on meteorological phenomena might be settled in a comparatively short space of time if the civilised countries of the world could agree to record all observations during a few years according to lunar instead of solar coordinates. Other problems will readily suggest themselves to you, and several might possibly be dealt with simultaneously.

The great reform I have in view is this :—Before you observe, make sure that your observations will be useful and will help to answer a definite question.

I hope that, though my frankly outspoken criticisms may not command universal assent, you will agree that there is some foundation for them, and, if so, the time is obviously not well chosen when observational science can be separated from its mathematical and experimental sisters. We hope that cosmical physics may remain an integral portion of Section A, and, though we acknowledge our weaknesses, we claim to have also something to teach.

I hope that our proceedings this week may show that we can put aside observational detail and throw some light on the great and important problems with which our science is concerned.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

ALTHOUGH the number of communications made to the Section at Belfast was less than at Glasgow last year, there was no decrease in the interest of the meetings. The inclusion of cosmical physics in the subjects dealt with by the department for astronomy materially increased the attendance at the meetings of that department.

In the mathematical department, Miss Hardcastle described the ground covered by the second part of her report on the present state of the theory of point groups, and stated that a further communication would be necessary to bring the report up to the present time. In the absence of the author, Prof. Forsyth gave a short account of Mr. E. T. Whittaker's solutions of the partial differential equations of mathematical physics. Mr. Whittaker finds that an expression of the type

$$\int_0^{2\pi} f(z + ix\cos u + iy\sin u, u)\, du$$

is the most general solution of the potential equation of Laplace, where f is an arbitrary function of the arguments

$$z + ix\cos u + iy\sin u \text{ and } u, \text{ and } i = \sqrt{-1}.$$

It follows that Legendre's, Bessel's and other well-known solutions of the equation are special forms of Mr. Whittaker's. In the same way, the general solution of the equation of wave motion is of the type

$$\int_0^{2\pi}\int_0^{\pi} f\left(x\sin u\cos v + y\sin u\sin v + z\cos u + \frac{t}{k}, u, v\right) du\, dv,$$

where f is an arbitrary function. Mr. Whittaker points out that this solution may be analysed into plane waves, and therefore supports the conclusion arrived at by Dr. Johnstone Stoney in 1897, that all disturbances in the ether can be resolved into trains of plane waves.

In the department of physics, Lord Rayleigh brought forward the question of the accurate conservation of weight in chemical reactions. He considered the discrepancies found by experimenters too large to allow the law of conservation to be accepted as proved, and hoped that the experiments at present being carried out by Landolt and Heydweiller would soon lead to a definite conclusion. Prof. Morton described the experiments he and Mr. Hawthorne had carried out on the motion of a detached thread of liquid in a capillary tube. He concludes from them that there is some force of the nature of an attraction between the liquid and the material of the tube, which must be taken into account to explain completely the phenomena observed. He further detailed how he had, in conjunction with Mr. Vinycomb, repeated and extended the work of Raps on the mode of vibration of stretched strings, and investigated the effect of the rigidity of the support on the motion of the string.

Dr. Barnes, of Montreal, on continuing his experiments on the critical velocity of flow of water through tubes, has found that the velocity varies with temperature in the way anticipated from the viscosity term in the expression given by Prof. Osborne Reynolds in his classical paper on critical velocity. By applying in the case of mercury the method used in determining the specific heat of water, he has also found that the specific heat of mercury decreases at a rate which itself decreases slightly with increase of temperature. Lord Kelvin sent a short communication in which he suggested that the temperature of an animal surrounded by a saturated atmosphere hotter than itself was kept down by evaporation within the lungs.

Dr. J. Larmor, in a paper on the application of the method of entropy to radiant energy, showed that by defining the entropy of a given space containing radiant energy distributed in any arbitrary way, as the logarithm of the probability of the existence of that particular distribution, the law of distribution of the energy with wave-length, which was recently deduced by Planck by considering a space filled with electrical resonators, could equally well be established. According to it, the amount of energy between wave-lengths λ and $\lambda + d\lambda$ radiated by a perfectly black body at absolute temperature t is proportional to

$$\frac{1}{\lambda^5}\,\frac{1}{e^{\frac{a}{\lambda t}} - 1}$$

where a is a constant.

Mr. Petavel gave an account of the work he had done towards the production of a standard of light. He considered that the incandescent surface of a metal of the platinum group heated electrically furnished the best source, and proposed to fix the temperature of that source by the equality of the radiation transmitted by suitable thicknesses of two media, the absorption of one of which (water) increased, and of the other (black fluorspar) decreased, with increase of temperature of the source. Dr. C. S. Myers called attention to a variation of pitch of Galton and other high-frequency whistles when the wind pressure was changed, which he had not been able to explain.

Lord Rayleigh prefaced a description of his own experiments to determine whether double refraction was produced in isotropic transparent bodies by their motion through the ether, by an account of those of Michelson and Morley. The latter led to the conclusion that light travelled with the same velocity, whether the direction of transmission was coincident with, across or opposed to that of the motion of the body. Lord Rayleigh's arrangement would have enabled a change of velocity of 10^{-10} of the velocity of light to be detected, but no change was observed when the light was transmitted through water or carbon bisulphide. The experiments on solids are not yet concluded.

Dr. Johnstone Stoney forwarded a note in which he showed that by substituting for Huyghen's wave surface, a wave film of finite thickness, within which the phases of the disturbances were given proper values, the disturbance propagated to a point outside the wave surface could be accurately calculated. In a second note, Dr. Stoney showed how his method of resolving the light traversing any isotropic medium into trains of plane waves might be applied to explain several optical phenomena which have not hitherto yielded to other methods.

Prof. E. Wilson described his experiments on the use of a magnetic detector in space telegraphy. His detector consists of an iron ring magnetised to instability by a current through a coil wound on the ring. The electric waves falling on the ring slightly disturb its magnetic state, and the disturbance is indicated by the sound produced in a telephone in series with a second coil wound on the ring. He finds such a detector very convenient and satisfactory in working.

Prof. Minchin has found that a coherer consisting of a carbon rod lightly supported in aluminium stirrups in an evacuated glass tube decoheres better than any other form he has tried, and is now engaged in applying the arrangement to long-distance transmission.

Dr. Marchant showed that the graphical method of determining the discharge of a condenser through a variable inductance gave results which agreed very closely with the calculated discharge in those cases in which the calculation could be carried out.

Mr. Butler-Burke gave a short account of his work on the phosphorescence produced in partially exhausted tubes by the passage of an alternating current round them. He concludes that it is due to the formation of groups consisting of a large number of molecules of gas within the tube.

In the department of astronomy and cosmical physics, Dr. W. E. Wilson exhibited a bolometer arranged to record solar radiation. It consists of two blackened coiled platinum wires, on one of which the light of the sun is allowed to fall through an opening in the metal box in which both are enclosed. The Rev. A. L. Cortie has examined in detail the Greenwich records of sun-spots and faculæ, and the diurnal ranges of the declination magnet, for the years 1899-1901, and finds that there is not sufficient accordance to support the statement sometimes made that sun-spots cause magnetic storms. He considers the two are correlated effects of some common cause still to be found.

The committee for investigating the upper atmosphere by means of kites gave a report of flights made from their station near Oban during July and August. The average height reached was about 3500 feet, and the average rate of decrease of temperature upwards about 3°·5 F. per 1000 feet.

Dr. Shaw, in his communication on radiation in meteorology, pointed out that radiation or absorption of heat by a cloud would result in motion of the cloud downwards or upwards. This motion would produce in its turn a heating or cooling of the cloud opposed to the initial change, and a much more careful and extended study of the radiation from clouds than had hitherto been attempted was necessary before several of the problems connected with cloud motion could be solved. He suggested several ways in which observers with simple instruments could help toward the solution of these problems.

Prof. Milne, in presenting the report of the Seismological Committee, stated that each of the recent West Indian eruptions had been preceded by sudden readjustments of the strata in the neighbourhood, which left their traces on the earthquake-recording instruments. This may, after further investigation, lead to a method of predicting eruptions.

Dr. Roberts exhibited photographs of nebulæ illustrating the nebular theory of the evolution of star systems, from cloudy nebulæ, through the spiral stage, to star clusters.

Mr. Hinks opened a discussion on the nebula surrounding Nova Persei by showing that some of the phenomena exhibited by the nebula might be due to its being ring-shaped. Photographs exhibited by Dr. Roberts did not, however, appear to support this view, and there seems little hope of coming to any definite conclusion as to the nature of the nebula until more information as to its appearance is available. C. H. LEES.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE total number of communications brought before Section C at Belfast was thirty-five. None of them can be said to have been of really great importance, but they were for the most part records of good work. The Committee on Life-zones in the Carboniferous Rocks sent in an admirable report of careful and systematic fossil-collecting. The Committees on the Underground Waters of N.W. Yorkshire and on Erratic Blocks were also able to show excellent work, and Prof. W. W. Watts, as usual, brought a good series of photographs which had been collected by his committee during the past year. Proceedings opened on Thursday, September 11, with the president's address, which has already been printed in our columns. It was followed by a lecture on the geology of the country around Belfast by Prof. Grenville A. J. Cole. On the morning of Sept. 15 Prof. Cole gave a second lecture, on the geological structure of Ireland; both lectures were illustrated by lantern slides and were listened to with close attention by large audiences. A considerable number of the papers naturally dealt with the geology of Ireland, and it may be convenient to notice them first and then to mention some of the other communications in geographical order. A proof-sheet of the Drift edition of the geological map of Ireland was exhibited by Mr. Teall, the director of the Survey. He explained that it was printed in colour instead of being hand-coloured, and was consequently clearer and would cost much less than the hand-coloured maps now issued by the Survey.

The post-Glacial deposits of the Belfast district were described in a most interesting paper by Mr. R. Lloyd Praeger. A peat bed, representing an old land surface, is found 20 feet below low water at Belfast, but between tides at other places in the district. In it remains of the Irish elk have been found, and a little above it there is some 12 feet of blue clay, the upper part of which contains *Thracia convexa* and other shells, indicating a warmer climate than the fauna now living in the Irish Sea and a depth of five to ten fathoms, whilst in the lower part of the clay, *Scrobicularia piperata* and fossils of a shore type are found.

Mr. P. F. Kendall read a paper by Madame Christen giving an account of the recent work of the Belfast Field Club. The members have made a careful study of the drifts of the district. They have, for example, proved the transport of the Rhyolite of Tardree to the north as well as in other directions. Attention was also drawn to the wide dispersal through the district of blocks from Ailsa Craig, and it was stated that these blocks are practically always found associated with marine shells. The committee appointed to explore Irish caves was able to show excellent work in the caves of Keishcorran Mountain, a mass of Carboniferous Limestone fifteen miles south of Sligo. In the Coffey Cave, bones of the Arctic lemming had been found in considerable numbers. This, the report states, is the first record of its existence as a former inhabitant of Ireland. Excavations in an extensive series of caves at Edenvale, county Clare, were described. Remains of bear and of the Irish elk were recorded, as well as human implements, ornaments, &c., and Mr. R. J. Ussher, who read the report, said that he hoped for important evidence of the state of prehistoric Ireland from further exploration.

Mr. Joseph Wright announced his discovery of large numbers of marine Foraminifera in Boulder-clay from various places in Ireland and also from England, Wales, Scotland, the Isle of Man and Canada. He more especially dealt with the Boulder-clay of Knock Glen, near Belfast. From it he had obtained seventy-nine species, and he suggested a considerable depression of the area at the time of its deposition. This led to an animated discussion, Prof. Boyd Dawkins supporting the author's view and Messrs. Lamplugh and Kendall contending for a transport of the clay to its present position by land ice.

A paper by Mr. R. Clark dealt with the Silurians of north-east Ireland. The author described some new fossil localities and gave lists of the species found.

Mr. G. Barrow read a paper on the prolongation of the Highland Border rocks into county Tyrone. The author referred to the Jasper and green-rock series, which he had found between Blairgowrie and Stonehaven (*Q.J.G.S.* vol. lvii. p. 328), and explained that he believed it to correspond with a series found by Mr. Peach near Omagh. He thought these rocks were intermediate in age between the Highland rocks, which he looked upon as Archæan, and a newer series, the Pomroy rocks, of Silurian age.

An interesting discussion followed the reading of this paper.

Mr. McHenry agreed that in Ireland there are three series:—(1) An old series, which he thought was probably metamorphosed Llandeilo and Bala; (2) the green rocks; and (3) the Pomroy rocks, which are mapped Lower Silurian, but contain Devonian and Wenlock fossils with a few survivors of Bala type. The conglomerates of this third series contain pebbles of the green rocks. He agreed that the line between the green rocks and the older series was a great thrust which in his opinion affected the Old Red Sandstone. He had followed it south-west to Castlebar and Clew Bay into Clare Island.

Mr. Teall agreed that this line of disturbance in Ireland should be classed with that which the author had worked out in Forfarshire, but he thought further evidence was required as to the age of the rocks. Dr. Matley, Prof. Cole, Prof. J. F. Blake and Mr. Cunningham-Craig also spoke. In reply, the author said he was sure of the order of succession, but not of the precise age of the rocks.

A list of 113 minerals known to occur in Ireland was contributed by Mr. H. J. Seymour. He explained that it was but of a preliminary character and that he had only included species which he was satisfied really have been found in the country.

Passing to Scottish geology, a paper of very great interest was sent in by Mr. Kynaston and was read by Mr. Teall. The author described a series of volcanic rocks in the district extending from Glen Coe to the Black Mount. The lower part consists of some 1500 feet of basic andesites with sandstone, shale and conglomerate at the base. Above these andesites are agglomerates and breccias capped by some 700 feet of hornblende andesite. Messrs. Peach and Tait have discovered plant remains in a bed of black shale associated with these lavas which enable the author to fix their age as Lower Old Red Sandstone; that is, they are of the same date as the great volcanic series of Lorn.

The author then showed that the granite of Ben Cruachan

s newer than these volcanic series, thus solving a question of considerable interest. From this it follows that the boulders of granite found in the basement conglomerate of the volcanic series are not derived from the granite of the district, but must have come from some other area.

Two papers were sent in by Dr. W. Mackie. The first dealt with the conditions under which manganese dioxide has been precipitated in the Elgin sandstone. The second gave the results of a series of determinations of the soluble chlorides and sulphates in the same sandstone, made with a view to test the theory that from such an examination it is possible to determine the character of the waters of the basin of deposit of sedimentary rocks. The result was of a negative character, and the author believes it is not safe to infer that the soluble salts of a deposit represent the salts of the original waters of the basin of deposition.

English geology occupied a very small part of the time of the Section. Mr. Horace B. Woodward sent an interesting note relating to the Eocenes. A section on a new railway between Axminster and Lyme Regis shows a good example of Bagshot strata near Combe Pyne Hill which serves to connect the beds of that age at Bournemouth with the deposit at Bovey Tracey in Devon. This last is now admitted to be of Bagshot age. It used to be called Miocene, but Mr. Starkie Gardner has long contended that it is equivalent to the Bournemouth Series.

A paper on the fossil flora of the Cumberland Coalfield was read by Mr. E. A. Newell Arber, who described plants from both the Whitehaven sandstone and the Coal-measures.

Mr. P. F. Kendall dealt with the Vale of Eden. He believed that he could show from the relative position of the Permian breccias or Brockrams that a movement of the Pennine faults had taken place in Permian times.

There was one paper relating to Wales. It was by Mr. W. G. Fernsides, who described some new faunas which he had obtained at Pen Morfa, near Tremadoc. He described a zone with species of high Lingula Flag type 30 feet below the Lower Tremadoc. Some 30 feet above the horizon of Ramsay's Lower Tremadoc fossils, he had found a continuous zone of Dictyonema, and had mapped its outcrop for more than five miles. Finally, some 400 feet above the Dictyonema, he had found a Shineton fauna with a number of Swedish forms and some new species.

Passing now to papers dealing with localities outside the British Isles, we may mention a paper by Dr. R. H. Traquair on fishes of the Lower Devonian roofing slate of Gemünden in Germany. They belong to the class with mailed bodies and are there associated with a fauna thoroughly marine in character, a point of considerable interest. The author showed some beautiful photographs of the fishes and of starfishes, crinoids, trilobites, corals, &c., from the slates.

Indian geology was dealt with in an interesting note by Prof. H. G. Seeley. He said that hitherto there has been no evidence of Cretaceous strata in the Salt Range of the north of India, but he was now able to bring forward an account of a series of species found by Mr. E. G. Fraser on the shoulder of Sekasar. They are of the type or age of the Upper Greensand.

Two papers dealt with Victoria, Australia. Mr. James Stirling gave some notes on a new geological map of the colony, and Dr. Smith Woodward sent an account of some observations on a new Lower Carboniferous fish-fauna from the Broken River. Attention was first drawn to these Broken River fossils some twelve years ago, and the late Sir Frederick M'Coy described them as a mixture of Devonian and Carboniferous forms. This Dr. Woodward now shows to have been a mistake; he considers them typically and essentially Carboniferous. Dr. Traquair said that he had seen the collection and could corroborate all the statements in the paper. Palæontologists might now congratulate themselves that the myth which alleged the existence of fishes of Lower and Upper Devonian and Lower Carboniferous types in the same bed had been exploded.

With regard to America, the only contribution was a paper by Dr. H. Woodward on the Middle Cambrian Trilobites of Mount Stephen, British Columbia.

Most of the Palæontological papers have already been noticed, but an interesting note on the tusks and skull of *Mastodon angustidens*, by Dr. C. W. Andrews, deserves mention.

Prof. J. Joly brought forward a suggestive paper on the viscous fusion of rock-forming minerals, which gave rise to an interesting discussion in which Mr. Teall, Prof. Grenville Cole and Dr. Johnston-Lavis took part.

Prof. J. F. Blake read a paper on the original form of sedimentary deposits. He observed that during the continuance of constant physical conditions, the seaward boundary of river-brought deposits will be a marked line. Such a line has been called an escarpment and the edge of the continental plateau, but the author believed it to be the limit of terrigenous deposits in bulk. He also considered that limestones are most likely to form deposits of lenticular shape with the long axis parallel to the shore, and when they are found to give place to shales we should infer that we are approaching a river or other source of sediment.

In conclusion, we may mention that a series of excursions to places of geological interest was arranged by Messrs. G. W. Lamplugh, J. St. J. Phillips and H. J. Seymour, and were much appreciated by the geologists present at the meeting.

CARBON AND PLANTS.[1]

IN a paper recently laid before the Royal Society, dealing with the physical processes which regulate the entry of atmospheric carbon dioxide into the leaves of plants,[2] the authors incidentally described a series of experiments relating to the rate of absorption of dilute gaseous carbon dioxide by surfaces of solutions of caustic alkali, when air containing definite small amounts of this gas is drawn over the liquid. Contrary to what might be expected from the perfect absorbing nature of the solution, and the known laws of gaseous diffusion, the amount of CO_2 absorbed by unit area of the liquid surface in unit time ceases sensibly to increase when a comparatively low velocity of the moving air current has been reached. This, however, only holds good when the proportion of CO_2 in the air stream is maintained quite constant, any slight variation in the amount at once affecting the rate of absorption. On investigation, it was found that for dilutions of carbon dioxide lying between 0·6 part and 6 parts per 10,000 of air, the rate of absorption of the carbon dioxide *is strictly proportional to its partial pressure.*

In determining the rates of gaseous diffusion of atmospheric carbon dioxide through multiperforate diaphragms extended over chambers containing perfect absorbents, the same relations between partial pressure of the gas and its absorption were found to hold good; under these conditions the amount of carbon dioxide passing through the diaphragm in a given time is also directly proportional to the density of that gas in the moving stream of air which flows over the outer surface of the diaphragm.

But this latter case exactly defines the physical conditions under which atmospheric carbon dioxide enters the tissue of a living leaf, the multiperforate diaphragm being represented by the cuticle and epidermis, pierced with numerous stomata, and the inner absorbing chamber by the intercellular spaces of the parenchyma, bounded by the chlorophyll-containing cells in which the process of photosynthesis goes on (*loc. cit.*).

The authors have now found, by enclosing the living leaves in glass cases through which air containing known proportions of CO_2 is passed, that a living leaf is really able, within certain limits, to respond to increased amounts of carbon dioxide in the air surrounding it, in such a manner as to indicate an approximate proportionality between the photosynthetic work it can accomplish and the partial pressure the gas exercises in the air bathing the leaf surface.

The following experiment may be selected from several, in illustration:—

Experiment I.—In this case, comparative experiments were made on two successive days in August, 1898, with two similar leaves, A and B of *Helianthus annuus* whilst still attached to the plant. These were exposed to the strong diffused light of a clear northern sky under as nearly as possible identical conditions, with the exception of the composition of the air drawn through the cases.

Over leaf A was drawn normal air containing 2·8 parts per 10,000 of CO_2, whilst the air passing over leaf B contained 25·53 parts CO_2 per 10,000.

[1] Abridged from a paper on "The Influence of Varying Amounts of Carbon Dioxide in the Air on the Photosynthetic Process of Leaves and on the Mode of Growth of Plants," by Dr. Horace T. Brown, F.R.S., and Mr. F. Escombe. Read before the Royal Society on May 29.

[2] *Phil. Trans.*, B. 1900, vol. cxciii. p 278.

Leaf A.

Area of leaf	743·1 sq. cm.
Volume of air passed per hour, reduced to normal temperature and pressure...	159·03 litres.
CO_2 content of air entering case ...	2·80 parts per 10,000.
,, ,, leaving case ...	1 64 ,, ,,
Mean CO_2 content of air in contact with leaf during experiment . .	2·22 ,, ,,
CO_2 absorbed by leaf per hour ...	18·44 c.c.
,, per sq. metre per hour	248 2 c.c.

Leaf B.

Area of leaf	863·75 sq. cm.
Volume of air passed per hour, reduced to normal temperature and pressure	72·7 litres.
CO_2 content of air entering case ...	25·30 parts per 1000
,, ,, leaving case ...	4 12 ,, ,,
Mean CO_2 content of air in contact with leaf during experiment ...	14 82 ,, ,,
CO_2 absorbed by leaf per hour ...	155·7 c.c.
,, per sq. metre per hour	1802 8 c.c.

It is manifest that if we wish to determine the relation of the partial pressures of carbon dioxide to the rate of intake of that gas into the leaf, we must employ the values representing the mean carbon dioxide content of the air in contact with the leaf during the experiment, which may be taken as the arithmetical mean of the composition of the entering and emergent air. In the above experiment, we obtain the following relations:—

Ratio of partial pressures of CO_2 in A and B, 2·22 : 14·82 or **1 : 6·6**.

Ratio of CO_2 absorbed per sq. metre of leaf A and B in one hour, 248 2 : 1802 8 = **1 : 7·2**.

Thus by increasing the amount of CO_2 in the air passing over the leaf about sevenfold, we have, under similar conditions of illumination, increased the photosynthetic power of the leaf by a little more than the same amount.

Experiments of this nature are necessarily limited to comparatively short periods, and give no information as to how far the plant, as a whole, will respond to such changes in its atmospheric environment. When first drawing attention to these facts in 1899 (Presidential Address, British Association, Section B, Dover), it was pointed out that we were not justified, without direct experiment, in concluding that the plant would be able to avail itself indefinitely of the increased amount of plastic carbohydrate material formed in its leaves under these artificial conditions, and that translocation, metabolism and growth may have become so intimately correlated that the perfect working of the entire plant may only be possible in an atmosphere containing the normal amount of three parts of CO_2 per 10,000.

Experiments were started to test how far slightly increased amounts of CO_2 in the air would affect the dry weight of plants grown in such atmospheres, and they indicate that the plants were certainly not stimulated to increased growth by somewhat increasing the amount of CO_2 in the surrounding air. The evidence, in fact, points in the other direction, *i.e.* towards a slight diminution in the increment of dry weight, and to a less development of foliar area. There were also indications of certain morphological differences, which assumed some importance in the light of subsequent experiments. The plants grown in air slightly enriched with CO_2 had not only smaller leaves than the controls, but these leaves were of a distinctly darker green, and the internodes of the plants were decidedly shorter.

The results obtained with these preliminary experiments now induced the authors to extend their observations to a larger number of species, and arrangements were consequently made to carry out a series of experiments on a large scale. This was done in a greenhouse divided in two by a glazed partition. In one half, the plants, gourds, balsams, fuchsias, begonias, &c., were exposed to the CO_2-laden atmosphere; in the other, control plants were in ordinary air. The original paper must be consulted for experimental details and precautions.

A careful record was made of the differences in appearance of the two sets of plants on June 10, June 29 and July 13, that is to say, at 28, 47 and 61 days from the commencement of the experiment. The results are given in detail in the appendix to this paper, and may be summarised as follows:—

The effect of an increased amount of CO_2 in the air becomes in most cases apparent within a week or ten days from the commencement of the experiment, and rapidly increases as time goes on. There is a marked difference induced in the habit and general appearance of most of the plants owing to a stimulation of all axial growth, accompanied by a more or less pronounced shortening and thickening of the internodes. Usually, but not in all cases, there is an increased number of the internodes, so that the height of the two contrasted sets remains much about the same, but the chief difference of general habit is brought about by the development throughout the plant of secondary axes in the axils of the leaves, thus giving the plants grown under the influence of increased CO_2 a denser and more bushy appearance. This was particularly noticeable in the fuchsias, especially the dark-leaved variety, in which every axil bore a shoot and frequently extra axillary ones. Adventitious shoots were also developed rather freely at the base of the plants.

The leaf area of the plants under the influence of increased CO_2 was generally found to be much reduced, not so much by the formation of a smaller number of leaves as by the reduction in area of the individual leaves. This was found to be extreme in the case of the dark-leaved fuchsias, and it was also very marked in the second crop of the leaves of Impatiens. There was also produced in many of the plants a marked inward curling of the leaves, the extremes in this direction being found in the begonias and fuchsias. In the dark-leaved variety of fuchsia, the leaves were curled inwards like a watch-spring, which would doubtless tend to reduce excessive photosynthesis by preventing the normal amount of light from reaching the chloroplasts. This change of habit may, in fact, be regarded as an attempt on the part of the plant to adapt itself to its abnormal atmospheric surroundings.

The extra CO_2 in several cases induced a deeper green colour in the leaf, and in all other parts of the plant where chlorophyll was present. This was particularly noticeable in the second crop of leaves developed on the Impatiens, in the begonias and in the darker-leaved fuchsias.

On July 19, the Sachs test for starch was applied to the leaves of the two varieties of fuchsia, *Cucurbita Pepo* and *Impatiens platypetala*. In all cases, the leaves taken from the plants grown with increased CO_2 in the air showed a much larger accumulation of starch than did the leaves of the control plants. These differences were the most strongly marked in the leaves of Impatiens, which became quite black with the test.

It was, however, in the development of the *reproductive organs* of the two sets of plants that the most striking and important differences were found. Whilst the control plants in ordinary air flowered, and in some cases fruited luxuriantly, in the corresponding plants submitted to air containing 11·4 parts per 10,000 of CO_2, *inflorescence was almost totally inhibited.* With the exception of one or two sickly-looking flowers on the begonias, not a single flower-bud opened on any of the plants of this set. The plants of Impatiens, Kalanchoë and of the darker-leaved fuchsias did not even produce a flower-bud, whilst in the Nicotiana, Cucurbitas and lighter-leaved fuchsias, the small flower-buds which commenced to form were completely shed long before the time of opening.

In another series of experiments, carried out on similar lines, the air of compartment B was enriched with carbon dioxide to the extent of 6 per cent., that is to say, up to about 200 times the normal amount. The experiment extended from June 3 to August 26, and the general results both in the direction and amount of change of habit induced in the plants were so very similar to those induced in the plants with only three-and-a-half times the normal amount of CO_2 as to require no further special description. The results are, however, valuable as indicating that the observed differences cannot be due to any *direct* poisonous influence of the carbon dioxide, otherwise we should certainly expect a marked difference to be produced by increasing the amount of CO_2 from 11·4 parts per 10,000 to 600 parts per 10,000, *i.e.* more than fiftyfold, which was not the case to any appreciable extent.

The direction in which we must search for the true explanation of the effect is probably indicated by the experiments on leaves described in the early part of the paper, where it was shown that the amount of photosynthesis in the leaf lamina is, within certain ill-defined limits, a function of the partial pressure of the CO_2 in the surrounding air.

In the first series of experiments in the greenhouse, where this partial pressure was maintained at about three-and-a-half times the normal, the plants for a certain limited period must

have been manufacturing carbohydrate material within their chloroplasts at least three-and-a-half times faster than those in normal air, and, although this rate of photosynthesis would perhaps not be maintained for very long, yet there would always be a general tendency for the carbohydrate supply in the leaves to be kept up to a higher point than in the controls grown in ordinary air, a fact which was shown by the leaves of set B always being gorged with starch.

Since it is quite certain that this increased photosynthesis does not to any material extent contribute to the increase of dry weight of the plants, we can only conclude that the transformation, translocation and general metabolism of the leaf-reserves under these conditions cannot keep pace with the increased tendency to produce an extra amount of plastic material from the atmosphere. Moreover, it is clear that the whole mechanism of the plant on which normal nutrition depends has its parts so completely and accurately correlated that any slight increase in the composition of the surrounding air which favours increased photosynthesis destroys the adjustment of the various parts and results in a more or less abnormal development of the plant. That any such disturbance of the economy of the plant should profoundly modify the reproductive functions might perhaps have been expected.

It is somewhat remarkable to find that all the species of flowering plants, without exception, which have been the subject of experiment appear to be accurately "tuned" to an atmospheric environment of 3 parts of CO_2 per 10,000, and that the response which they make to slight increases in this amount are in a direction altogether unfavourable to their growth and reproduction. It is not too much to say that a comparatively sudden increase of carbon dioxide in the air to an extent of about two or three times the present amount would result in the speedy destruction of nearly all our flowering plants.

To a certain extent, we may regard the facts recorded in this paper as indicating that the composition of our atmosphere as regards its carbon dioxide has remained constant, or practically constant, for a long period of time, but the authors leave altogether untouched the question of any variations of a secular kind. All we are justified in concluding is that if such atmospheric variations have occurred since the advent of flowering plants, they must have taken place so slowly as never to outrun the possible adaptation of the plants to their changing conditions.

MAGNETO-OPTICAL ROTATION IN THE INTERIOR OF ABSORPTION BANDS.

AN interesting confirmation of Voigt's theory of absorption has been afforded by an experiment by Prof. Zeeman, described in the *Proceedings* of the Amsterdam Academy of Sciences of June 25. In Voigt's theory, the separation of a spectral line by the action of a magnetic field is found as the separation of an absorption line, and the theory requires a negative rotation of the plane of polarisation in the interior of the absorption band. Now in previous experiments, such as those of Corbino, the only observed result has been a very small positive rotation. The new experiment described by Prof. Zeeman is interesting, not only as showing the existence of a negative rotation in the interior of an absorption band, but also as being in perfect quantitative agreement with Voigt's theory.

By means of a system of quartz prisms such as have been used by Fresnel in his experiment on the division of a plane polarised ray into two circularly polarised rays, a number of interference fringes were formed at right angles to the bands of a spectrum, and when light from a bright source was allowed to pass through sodium vapour and analysed with a Nicol's prism, the effect produced by the sodium absorption lines and the interference lines combined was as shown in Fig. 1. If, however, the sodium vapour was subjected to the action of a powerful magnetic field, of from fifteen to twenty thousand units, the effects shown in Fig. 2 were observed. It will be noticed that the fringes moved upwards along the components of the doublets, whereas the parts of the fringes *between* the components became disconnected from the exterior parts and *moved downwards*. As the density of the sodium was increased, the interior portions slid downwards with increasing velocity, and at a certain stage those in the interior, more particularly of the D_1 line, resembled inverted arrows. At last with increasing proportions of sodium these arrows entirely disappeared, and it was observed that this disappearance was more rapid with the D_2 lines than with the D_1 lines. Among subsidiary features it was noticed that the slope of the interior interference fringes is greater towards the side of the greater wave-lengths than towards the violet. The interior fringes also show a slight asymmetry, so that, *e.g.*, the points of the arrows in Fig. 2 ought to be asymmetrical.

Using very much denser vapours, however, results were obtained agreeing more with the experiments of Macaluso and Corbino. Figs. 3 and 4 show the effects with field intensities of about 4500 and 10,700 units respectively, and the absorption bands appear to contain horizontal parts of an interference fringe which have undergone a very small displacement *upwards* by the action of the field. These horizontal parts are, however, broader and more ill defined than the markings in the circumstances previously described. It is possible that the conditions assumed in these later experiments are different from those required by the theory, and that some explanation of the difference in the two kinds of phenomena may be found.

D_2 D_1

FIG. 3.

D_2 D_1

FIG. 4.

In a paper communicated to the Reale Accademia dei Lincei of Rome, also on May 31, Prof. W. Voigt discusses the same phenomenon on a theoretical basis, and quotes the formula

$$n\chi = \mathrm{KP}\ \frac{(\Delta^2 - \mathrm{P}^2 - 1)}{(\Delta^2 + \mathrm{P}^2 + 1)^2 - 4\Delta^2\mathrm{P}^2}.$$

where χ denotes the angular rotation of the plane of polarisation, n the geometrical mean of the indices of refraction of the two waves propagated in the vapour, P is proportional to the magnetic field, and Δ is proportional to the number of wave-lengths in the distance of the point considered from the primitive position of the absorption band. From this formula are obtained the curves shown in Fig. 5, which correspond to the

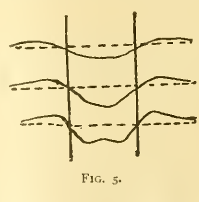

FIG. 5.

values $P = 0{\cdot}5$, $P = 1{\cdot}5$, $P = 3{\cdot}0$, and the resemblance between these curves and Prof. Zeeman's photographs will be readily noticed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following is the letter of congratulation, written by the Public Orator, Dr. Sandys, on behalf of the University of Cambridge, and presented to the University of Christiania by Prof. A. R. Forsyth, F.R.S., the delegate appointed to represent the University of Cambridge on the occasion of the recent commemoration of the centenary of the birth of Niels Henrik Abel:—"Litterae vestrae, viri doctissimi, ad nos nuper perlatae sunt, in quibus certiores facti sumus, annum centesimum ex eo quo natus est alumnus vester insignis, Nicolaus Henricus Abel, Universitatem vestram Nonis Septembribus esse celebraturam. Alumnus ille vester, ut studiorum mathematicorum inter peritos ubique constat, inter scientiae illius ipsos principes merito iamdudum numeratus est, neque in sua tantum vita, intra annorum septem et viginti spatium angustum, nomen immortale est adeptus, sed etiam saeculo in eodem inter Europae gentes scientiae analyticae cultoribus plurimis novos stimulos indidit, et studiorum suorum ad regiones novas explorandas excitavit; e quibus unus, non secus atque alumnus ille vester, provinciae suae pulchritudine singulari commotus, existimavit 'functiones ellipticas non aliis adnumerari debere transcendentibus, sed speciem quandam iis inesse perfecti et absoluti.' Iuvat vitae illius annales ab uno e professoribus vestris summa cum scientia, summa cum humanitate, conscriptos evolvere; iuvat inter socios illius exteros, unum audire suis laudibus, suis laboribus omnibus illum maiorem esse dicentem; alterum, ab illo temporis exigui intra terminos 'monumentum aere perennius' esse exactum, quod indicaret quantum ex ingenio eius sperare licuisset, 'ni fata obstitissent'; iuvat nos quoque inter praeceptores nostros nonnullos numerare, qui alumni vestri vestigiis institerunt, alumni vestri famam indies latius extenderunt. Unum ex eis, etiam in Scandinavia horum studiorum cultoribus non ignotum, nuntium et legatum ad vos honoris causa mittimus, qui nostrum omnium vota optima ad vos perferat, et nostrum omnium nomine viri tanti memoriae celebrandae laetus intersit. Valete."

Mr. R. P. Gregory, St. John's, has been appointed a demonstrator in botany.

The following have been elected to fellowships at Trinity College:—A. E. A. Watt Smyth, P. V. Bevan, O. W. Richardson, F. J. Pollock.

Dr. D. MacAlister has been appointed assessor to the regius professor of physic; Prof. Thomson, F.R.S., an elector to the Isaac Newton studentship in physical astronomy; Mr. J. B. Peace, Emmanuel, demonstrator of mechanism and applied mechanics; and Mr. R. C. Punnett, Caius, demonstrator of comparative anatomy. Mr. Punnett has also been elected to a fellowship at his college.

IT is stated in the *British Medical Journal* that Prof. Johannes Orth, of Göttingen, has been invited to succeed Prof. Virchow in the chair of pathology at Berlin.

THE following appointments have been made at the Hartley University College, Southampton:—Assistant lecturer in physics, Mr. O. W. Griffith; assistant lecturer in electrical engineering, Mr. E. H. Dixon; assistant lecturer in civil engineering, Mr. R. Baldwin Wiseman.

As already announced, the Manchester School of Technology is to be opened by Mr. Balfour as we go to press with this number. The school has occupied about seven years in building, and represents an endowment of nearly 300,000*l*., largely, but not entirely, of municipal origin. A sum of no less than 25,000*l*. has been expended upon the plant of the department of mechanical engineering alone, and the other departments have been equipped in the same liberal spirit. The city of Manchester thus possesses a technical school which should become an important factor of national progress.

WE have received the calendar of the Bristol Merchant Venturers' Technical College, which contains many illustrations of the workshops and laboratories in that institution. The College provides full courses of training in mechanical, electrical and sanitary engineering, and also prepares students for the B.Sc. examinations of the University of London in the faculties of science, engineering and economics. There are courses of training in the various branches of applied chemistry, including metallurgy, and special classes for persons intending to became architects, builders or surveyors. There is also a navigation department, a school for boys, and numerous evening classes.

THE Clothworkers' scholarship of 60*l*. a year for three years, awarded on the results of the matriculation or entrance examination of the Central Technical College of the City and Guilds of London Institute, has been awarded to W. H. Grinsted, from Horsham Grammar School, who obtained first place at the examination. Free studentships have been awarded by the Institute to W. M. Hooton, from King's Lynn Municipal Technical School, L. G. Morse, from Marlborough College, and H. K. B. Reed, from the South-Western Polytechnic, who came next in order of merit.

AN address on the reorganised University of London was given by Sir Arthur Rücker, F.R.S., at the opening of the winter session of St. Mary's Hospital Medical School on October 3. Referring to the educational equipment of London, he remarked that "it was and is in many respects inferior to what is provided, not only in Germany and America, but in our own provinces. There is not a single laboratory in the metropolis devoted to pure chemistry and physics which will compare in magnitude or in the perfection of its details with some of those which exist elsewhere." The hope was expressed that the teaching of the sciences connected with medicine would be combined with research; so that the University should contribute directly to the advancement of knowledge, and graduates of foreign and colonial universities might be attracted to London to study in research laboratories like those of the recently established physiological department of the University.

THE proceedings at Oxford on October 8 and 9 in connection with the Bodleian tercentenary were marked both by their enthusiasm and by their picturesqueness. Among the multitude of distinguished guests were representatives of the universities, libraries and learned societies in every part of the world. On the evening of October 8, a reception by the Provost of Oriel, in his capacity of Vice-Chancellor of the University, took place in the Ashmolean Museum, where Mr. A. J. Evans exhibited a number of drawings, photographs, plans and casts illustrating the excavations at Knossos, in Crete. On the following morning, a congregation, presided over by the Vice-Chancellor, was held for the purpose of conferring degrees upon certain of the eminent persons present as guests of the University, for receiving congratulatory addresses on the tercentenary of Sir Thomas Bodley's library, and for welcoming the visitors by the Public Orator, Dr. Merry. Among the honorary degrees, that of doctor of science conferred upon Prof. C. S. Minot, professor of histology and human embryology at Harvard University, may be mentioned as indicating that the claims of science were not forgotten. The congratulatory addresses, handed to the Vice-Chancellor by the delegates appointed for the purpose by the university or learned society they represented, were numerous, the list of universities and learned bodies presenting addresses included the following names:—Universities of Cambridge, Dublin, London, Birmingham, Durham, Wales, Edinburgh, Aberdeen, Glasgow, Toronto, Montreal (McGill), Sydney, Allahabad, Cape Town, Paris, Caen, Lille, Nancy, Breslau, Giessen, Göttingen, Leipzig, Kiel, Brussels, Ghent, Louvain, Cracow, Gratz, Copenhagen, Lund, Stockholm, Upsala, Geneva, Lausanne, Harvard, Cornell, Yale, Princeton, Columbia, Pennsylvania, Ireland (Royal), St. Andrews and Victoria, Royal Society, Royal College of Physicians, Royal College of Surgeons, Royal Geographical Society, Royal Irish Academy, Asiatic Society of Bengal, Royal Society of Sciences, Göttingen, Accademia dei Lincei, Rome, and Academy of Sciences, Vienna. After the congregation came the formal visit to the Bodleian Library. No preparations had been made, and the visitors found the Library wearing its every-day aspect. The celebrations were brought to a close by a dinner at Christ Church.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 29.—M. Bouquet de la Grye in the chair.—New experiments on the limit of intensity of current from a battery which corresponds to external electrolytic work apparent in a voltameter, by M. Berthelot. In a circuit consisting of one or more Daniell cells and a voltameter, the external resistance was increased until the gas resulting from the electrolysis was barely perceptible, and the limiting value determined. From these and earlier experiments on the same

subject, the conclusion is drawn that in electrolysis chemical energy is always necessary to commence the action, but not to maintain it. The preparation and properties of a new silicide of vanadium, by MM. H. Moissan and Holt. On heating silicon with an excess of vanadium trioxide in the electric furnace for some time, the silicide VSi_2, previously described, is obtained, which is stable in the presence of an excess of silicon. Another silicide, of the composition V_2Si, has been obtained in three ways—by the interaction of vanadium trioxide (120 grams) and silicon (14 grams), of silicon and vanadium carbide, or of the trioxide, silicon and copper, in all cases in the electric furnace. The new silicide is more infusible than the silicide VSi_2, from which it can also be distinguished by its colour, density, action with hydrochloric acid and easy decomposition on fusion with silicon.—On double fertilisation in the Cruciferæ, by M. L. Guignard. The phenomenon of double fertilisation can be followed completely in *Lepidium sativum* and *Capsella Bursa pastoris*, a detailed description of the stages being given.—Observations of the Perrine-Borrelly comet (1902 *b*), made with the Brunner equatorial at the Observatory of Lyons, by M. J. Guillaume.—The organisation of automatic spectrographs at the Observatory of Meudon, registering the radial movements and the thickness of the solar chromosphere, by M. H. Deslandres. The apparatus briefly described produces on the same plate ninety small spectra giving the radial velocity and thickness at 180 points on the sun's edge. These points are united on a circle of 95 mm. diameter. So far, it has not been possible to make continuous records on account of the expense; similar equipments at different parts of the world are also necessary for complete results.—On the continuous deformation of surfaces, by M. G. Tzitzéica.—On nitro-pyromucic acid and its ethyl ester, and on dinitrofurfurane, by M. R. Marquis. A mixture of nitric acid and acetic anhydride has been found especially serviceable in nitrating in the furfurane series. With ethyl pyromucate a mononitro derivative is readily obtained.—On the saponification of nitric esters, by MM. Leo Vignon and I. Bay. The results of experiments on the hydrolysis of various nitrates by sulphuric acid and by soda. The reaction is complex, nitrous acid and occasionally ammonia being produced.—On the utilisation of mineral substances by grafted plants, by MM. Lucien Daniel and V. Thomas. Transpiration is greater in the host than in the grafted plants, the total quantity of mineral material absorbed being considerably modified as a result of the grafting. It was also found that one effect of grafting was to profoundly modify the phenomenon of chlorosis.—On the caoutchouc-producing Landolphia of the French Congo, by M. Auguste Chevalier.—The earthquake at Salonica, by M. Christomanos. The earthquake of July 5, the epicentre of which was between Salonica and Gouvesno, was not of volcanic origin. Its effects were felt at great distances and for several days, hence it is probable that the seismic focus was at a great depth.

October 6.—M. Bouquet de la Grye in the chair.—Remarks by M. Appell on the third volume of his "Traité de Mécanique rationelle."—Observations on the sun made at the Observatory of Lyons with the 16 cm. equatorial during the first quarter of 1902, by M. J. Guillaume. The number of observations is smaller than usual owing to the unfavourable atmospheric conditions. Tables are given showing the number of spots, their distribution in latitude and the distribution of the faculæ in latitude.—Comparison of the tables of Vesta with the meridional observations made between 1890 and 1900, by M. Gustave Leveau.—Remarks on a problem of Clebsch on the movement of a solid body in an indefinite liquid, and on the problem of M. de Brun.—On a theorem of M. Frobenius, by M. de Séguier.—On a derivative of hydrogen peroxide, by M. R. Fosse. The reactions of dinaphthopyranol towards zinc dust, alcohol, pyrogallol and potassium iodide show that it behaves rather as a derivative of hydrogen peroxide than as an alcohol.—The synthesis of some tertiary alcohols; diphenylcarbinols, by M. H. Masson. The results of the action of magnesium phenyl-bromide upon a series of esters is given in summary, with a list of the alcohols and hydrocarbons obtained and their boiling points.—Anhydrous copper-ammonium sulphates, by M. Bouzat. A thermochemical paper.—On the examination and estimation of extract of chestnut wood mixed with oak extract, by M. Ferdinand Jean. The method is based on the fact that extract of chestnut sets free iodine from iodic acid, whilst extract of oak bark has not this property.—On the pectic fermentation, by M. Goyaud. Pectise forms pectic acid at the expense of the pectin. The phenomenon is not qualitatively influenced by the presence or absence of calcium salts.—The elaboration of venogen and of venom in the parotoid gland of *Vipera Aspis*, by by M. L. Launoy. The snake poison is formed in the cells of the parotoid gland of *Vipera Aspis* in two phases—the nuclear phase, with formation of grains of venogen, and the cytoplasmic phase, in which the venogen is transformed into the venom.—Palæontological researches in Patagonia, by M. André Tournouër.—On an enormous carnivorous mammal found in the plastic clay of Vaugirard, near Paris, by M. Marcellin Boule.

CONTENTS.

THURSDAY, OCTOBER 23, 1902.

THE ENCYCLOPÆDIA BRITANNICA.

The Encyclopaedia Britannica, vols. xxviii. and xxix. Being the Fourth and Fifth of the New Volumes. Ele–Gla. Pp. xix + 742. Gla–Jut. Pp. xx + 763. (London: A. and C. Black, and the *Times*, 1902.)

THE prefatory essay to vol. xxviii. is by Sir Leslie Stephen upon the subject of "The Growth of Toleration." It is pointed out that one dominant factor in the development which has taken place has been the growth of the natural sciences; and reference is made to the influence exerted by scientific investigation upon traditional beliefs and dogmas. Mr. Benjamin Kidd contributes to vol. xxix. a prefatory essay on "The Application of the Doctrine of Evolution to Sociological Theory and Problems."

There are many scientific articles in the two volumes, several being of great importance. Among the articles to which attention must be directed are the following:—Vol. xxviii.: Electricity and electricity supply, by Prof. J. A. Fleming, Mr. W. C. D. Whetham, Prof. J. J. Thomson, Dr. L. Duncan and Mr. E. Garcke; electrochemistry, Mr. W. G. McMillan; electromagnets, Prof. J. A. Fleming; embryology, Mr. Adam Sedgwick and Dr. A. E. Driesch; energetics, Dr. J. Larmor; engines, Prof. J. A. Ewing; England and Wales (geography), Dr. H. R. Mill; Entomostraca, Rev. T. R. R. Stebbing; evolution, Dr. Chalmers Mitchell; fisheries, Mr. W. Garstang; forests and forestry, Prof. W. Schlich and Mr. G. Pinchot (United States); Fourier's series, Dr. E. W. Hobson; analytic functions, Mr. H. F. Baker; functions of real variables, Prof. A. E. H. Love; fungi, Prof. Marshall Ward; fusion, Prof. H. L. Callendar; gas and gas lighting, Prof. V. B. Lewes; gaseous fuel, Prof. G. Lunge; artificial gems, Sir William Crookes; geography, Dr. H. R. Mill; geology, Sir Archibald Geikie; geometrical continuity, Rev. Charles Taylor; line geometry, Mr. J. H. Grace, and non-Euclidean geometry, the Hon. A. A. W. Russell. Vol. xxix.: Theory of groups, Prof. W. Burnside; gunnery, and gyroscope, Prof. A. G. Greenhill; gymnosperms, Mr. A. C. Seward; halos, the late Prof. P. G. Tait; Helmholtz, Prof. J. G. McKendrick; hemichorda, and hydrozoa, Dr. G. H. Fowler; heredity, and hybridism, Dr. P. Chalmers Mitchell; Huxley, Sir W. T. Thiselton-Dyer; hygiene, Colonel J. Lane Notter; ichthyology, Dr. A. Günther; insects, Dr. D. Sharp; iron and steel, Prof. H. M. Howe; irrigation, Sir Colin Campbell Scott-Moncrieff.

It is impossible to describe the whole of these articles in a notice of limited length, but from this group of scientific contributions to the "Encyclopædia" we select a few for brief notice.

So large a part, nearly one-sixth, of vol. xxviii. is devoted to electrical subjects that we cannot, with the space at our disposal, do much more than enumerate the branches treated. Under the heading "Electricity," Prof. Fleming writes on electric conduction, current and units; Prof. J. J. Thomson on discharge through gases and electric waves; and Mr. Whetham on electrolytic conduction. These articles cover the greater part of electrical theory; the practical applications are dealt with in separate contributions. Mr. Whetham's discussion of electrolytic conduction gives a full and favourable account of the dissociation theory; the student has therefore an opportunity, from this article and from that by Prof. Armstrong on "Chemistry," of considering both sides of the question. The electrochemist is indeed particularly well catered for in the new volumes, since, in addition to the articles already mentioned, Mr. McMillan contributes two articles to the present volume on "Electrochemistry" and "Electrometallurgy." These deal with the industrial applications, the first with refining of metals, electrotyping and plating, and alkali and chlorate manufacture; and the second with furnace processes, such as the production of aluminium and calcium carbide. A contribution on "Electromagnet," written by Prof. Fleming, discusses magnetic flux, permeability and hysteresis. A long article on "Electricity Supply" deals with the principle of lighting by arc and incandescent lamps, with electric traction, and with the commercial aspects of the industrial development of electricity. The treatment of electric traction is hardly adequate if this is all that is to be given in the "Encyclopædia"; for one thing, the article is entirely without illustration, a great disadvantage to the general reader. It is also to be noticed that there is a certain amount of repetition which might have been avoided; thus, the theory of the arc is discussed at some length by both Prof. Fleming and Prof. J. J. Thomson.

"Energetics" is a name commonly associated with a philosophy which proposes to abolish Newton's laws of motion and to deduce all the equations of dynamics from the single equation of energy. Dr. Larmor's article deals with a much more useful field of study, including Carnot's principle, the general thermodynamical equations, free and available energy, and Gibbs's important work on the equilibrium of chemical systems. It forms an excellent introduction to the study of thermochemistry.

Pure mathematics is well represented in the present volumes. In an article on the "Error Law," Mr. Edgworth gives an account of the various proofs of the common law of error and of Prof. Weldon's experimental verification, corrections for cases in which the number of elements is finite, normal and abnormal correlation, and applications to various problems in statistics. In the account of Fourier's series, Dr. Hobson divides the historical development of the theory of the representation of functions by trigonometric series into three periods, the first period opening with the work of D'Alembert, Bernouilli and others in connection with vibrations of strings, the second with Fourier's memoir of 1807 on the "Theory of Heat," and the modern period being inaugurated by Riemann's memoir of 1867. The article on "Analytic Functions" contains a good general account of Weierstrass's methods; that on "Functions of Real Variables" deals largely with the *continuum* of real numbers, the domain of a variable, the doctrine of continuity, and the questions of differentiability and integrability of functions. Under "Line Geometry," we have a discussion of the properties of linear and non-linear complexes, congruences and ruled surfaces. In the article on "Non-Euclidean Geometry," Mr. Russell traces the genesis of this important branch of pure

mathematics out of the attempts of mathematicians to improve the theory of parallels. A historical account is given of the development of the new geometry by Gauss, Lobatchewsky, Bolyai, Riemann and Beltrami. Considerable attention is given to the three prevailing misconceptions which have retarded the development of the subject, namely, the introduction of a fourth dimension in connection with the notion of curvature of space, the projective definitions of distance and angle, and the necessity for introducing rigid bodies in geometry.

The writer of the article on evolution has had a difficult task, with which, on the whole, he has grappled successfully. We miss, however, any clear presentment of the crucial point on which the controversies that at present divide evolutionists indisputably turn—viz. that of the transmission or otherwise of modifications due to individual plasticity. It seems inadequate to say, without explanation, that "the weakness of the neo-Lamarckian view lies in its interpretation of heredity," when, as a matter of fact, the whole neo-Lamarckian fabric must fall unless the reality of such transmission can be established. The summaries given of several modern developments of evolutionary theory are scarcely full enough to be of much value to the specialist, while the unskilled but intelligent reader in search of information, whose requirements should always be kept in view in a work like the present, will, we fear, find their language often too technical to give him what he wants. The writer tells us that

"multiradial apocentricities lie at the root of many of the phenomena that have been grouped under the designation of *Convergence*."

We should say rather that the first phrase merely repeats the idea of the second in a more cumbrous form. Moreover, we doubt whether anyone not an expert would grasp the meaning of either expression, or that of "homogeneous homoplasies," without illustration. The account given of the recent departure in biometrics is good so far as it goes, and the position of its exponents is not unfairly stated; justice, however, is hardly done to the fact that the quantitative stage is inevitable in any inquiry the material of which admits of measurement. Workers in this department are fully alive to the danger pointed out by Dr. Mitchell, and analysis of composite characters is making progress under the stimulus supplied by the rediscovery of Mendel.

The article dealing with forests and forestry is in two parts, the general part by Dr. Schlich, C.I.E., F.R.S., and that referring to the United States of America by Mr. Gifford Pinchot, Forester of the U.S. Department of Agriculture.

Dr. Schlich first deals with the general distribution of forests throughout the world, and this might with advantage be more detailed. His account of the utility of forests based on their indirect and direct advantages is admirable, the former being chiefly the prevention of the denudation of hill-sides and of the consequent flooding of low-land and the silting-up of river-beds. The direct utility of forests increases steadily with the population of civilised countries, and it is a remarkable proof of the effects of economic progress that whereas in 1880 Germany produced as much timber as she required, in 1899 she imported 4,600,000 tons, valued at 14,000,000*l.* and this in spite of the increasing yield-capacity of her State forests. The latter comprise about one-third of her forest area, but as continental communal forests are chiefly managed by the State, it is a pity that they are not separated from private forests in the table of areas, for continental private forests are frequently no better managed than our own. Eighty-seven per cent. of the timber we import yearly, worth about 22,000,000*l.*, is coniferous, and it is chiefly on Canada, with 1,250,000 square miles of forests, that the world will have to depend for the future. Curiously, the table showing movements of timber within the British Empire entirely omits Canada.

Dr. Schlich appeals to the landowners of Britain to afforest 3,000,000 of our 24,000,000 acres of lands either waste or used for light hill grazing, and for more attention to forestry by our colonies, most of which are no better than Canada in this respect. He gives an interesting account of forest management in India, the managed State forests of which, comprising, in 1900, 95,000 square miles, 10 per cent. of the area of British India, yielded (1890–95) an average net revenue, which is steadily increasing, of 73,70,000 rupees. Progress in forestry is also being made in South Africa and Ceylon.

Mr. Pinchot gives a good summary and a map of the distribution of forests in the United States, the chief causes of destruction of which are over-lumbering and fires. He gives a map of the present State reserved forests, which, although amounting in area to 72,500 square miles, look inconspicuous on the huge territory of 3,500,000 square miles. He has also drawn up a useful history of the State protection of forests, which was greatly assisted by the large reservations carried out by President Cleveland and the forest law passed in 1897, the general purport of which he explains and praises.

Forest education has progressed in America, forestry being taught at several universities and other institutions. Mr. Pinchot states, however, that European forestry is not yet applicable to America, but that the production of a net revenue and the perpetuation of the forest are the chief objects of the private forest owner, who is the principal timber producer in the States. There is an account given of the lumber trade, and the ominous note occurs that numbers of the eastern white pine lumber- and mill- men have removed to the southern States and Pacific Coast, driven away by the exhaustion of their supplies. From Dr. Schlich we learn that already the United States imports from Canada nearly as much timber as it exports.

The article "Geology" is written happily by the same authority, Sir Archibald Geikie, who contributed the elaborate essay in vol. x. of the ninth edition. He divides his subject as before into sections, and reviews in the same lucid manner the general progress made during the interval. In its cosmical aspects, the record is not, however, one wholly of progress, as Croll's astronomical theory is no longer considered to afford a solution of the problem of the Ice age. Many have dealt with the question of the earth's age, notably Sir A. Geikie, and we cannot wonder that he repeats his protest against the time-restrictions of physicists and mathematicians. No evidence of progressive diminution of activity, whether of

the sea or of volcanoes, is preserved among the rocks; their record, indeed, is one of singular uniformity, despite the catastrophes of Krakatoa in Sunda Strait and of Bandai-san in Japan, to which attention is directed. Much has also been learnt about fissure-eruptions. Here we are in touch with the author's special subject, and he devotes a considerable space to the volcanic history of the British Isles. To petrography, which no doubt is dealt with in a special article, but brief reference is made.

A glance at the article on geography shows how intimately it has become linked with geology during the past quarter of a century, thanks to the labours of Suess, Penck, Lapworth and W. M. Davis. The fact that the surface of the sea preserves no uniformity, and that it may locally rise and fall to a considerable extent without change in the lithosphere, would seem to revolutionise our ideas about raised beaches and submerged forests; but the author points to certain regions where there is definite evidence of slow upheaval or depression of land. The indications of changes of level derived from a study of coral-reefs are also discussed.

Structural geology naturally occupies some space, and special reference is made to the great flexures and overthrusts that have been determined in many regions. Palæontological zones receive attention, for on this subject great progress has been made, and although we miss reference to the brilliant researches of Dr. A. W. Rowe, the importance of the subject is fully admitted. We agree with the author that there is much yet to be solved in the problem of life-zones. Special mention might have been made of observations on radiolarian chert, but in so complex and many-sided a subject as geology we feel that the author has done all that could well be done to illustrate its progress in a limited space.

Prof. Greenhill's two contributions on ballistics and the gyroscope and gyrostat are full of material of interest to students of dynamics. In a short essay Sir W. T. Thiselton-Dyer summarises the chief points of Huxley's life and work, and contrives to express the essential characters of each in a few pages. Dr. Günther has brought the article on fishes up to date. In 1870 the number of known species of living fishes was stated as 8525, but since then it has been nearly doubled. Knowledge of the distribution, organisation and development of fishes has also made substantial progress, and Dr. Günther gives a survey of the most important advances.

The article on insects is by Dr. David Sharp, whose general knowledge of the subject is probably more extensive than that of any other living entomologist. Nevertheless, it is obvious that the space at his disposal was utterly inadequate to permit of his attempting more than a mere glance at a few of the more interesting matters connected with entomology that have been discussed in recent years. Among these are the number of species of insects; antiquity; duration of life (inadequately discussed; but the fact of a water-beetle living five and a half years in captivity was new to us, though some of Lord Avebury's Queen ants have attained a much greater age); economic entomology (with special reference to Coccidæ, and to insects and malaria); luminosity (concerning which Dr. Sharp remarks, "The light given by insects has been shown to be highly economical, and if a similar illuminating agent can be produced artificially it will be a great boon." Granted; but then there is the immense initial difficulty of producing or imitating organic chemical substances artificially); galls; anatomy and morphology (with special reference to the structure of the segments of the head); metamorphosis; classification (twenty-two orders are now recognised, the sequence of which differs considerably from that followed in the author's "Cambridge Natural History," published in 1899) and ethology (referring to intelligence and to social insects). The article concludes with a paragraph of "authorities," including references to a few recently published books and papers on insects; but the list is necessarily so short and incomplete that we think it might almost as well have been omitted altogether.

Though limitations of space have prevented some of the writers from doing full justice to their subjects, the volumes are rich in matter of interest to the student of science, and furnish substantial evidence of progress in many branches of natural knowledge.

THE STUDY OF THE PROTISTA.

Archiv für Protistenkunde. Herausgegeben von Dr. Fritz Schaudinn. Band i. Heft 1. Pp. 192; 5 plates. (Jena: Gustav Fischer, 1902.) Price Mk. 24.

OF late years very rapid progress has been made in our knowledge of that vast assemblage of organisms for which Haeckel set up a special "kingdom" or *Reich* with the name Protista, comprising the simplest living creatures amongst which the distinction of plant and animal is of quite secondary importance. In no branch of biology do works become so quickly out of date as in that which deals with the lowest forms of life. The attention which the Protista have received has been stimulated from two sources. From a purely scientific and theoretical point of view, it is evident that many elementary problems, or fundamental phenomena, of life can be studied in their simplest form, divested of unessential complications, in these lowly organisms. This is especially true of the facts of cytology relating to the structure and activities of cells. The discoveries of the last decade of the nineteenth century have revealed a remarkable uniformity, underlying the greatest variety in form and detail, in the cell-processes of the higher animals and plants, which cannot be considered as satisfactorily understood until the steps are made clear by which they have been evolved from the usually simpler, but in any case far more diversified, types of structure or development which are found to occur in unicellular organisms. It is only necessary to refer to the problems of cell-division and fertilisation in support of this proposition. Quite apart, however, from their claims on the attention of scientific biologists, the Protista are becoming continually more important as objects of study from the practical point of view. Some, as, for instance, the organisms of fermentation, are indispensable for human arts and manufactures; others have a claim to consideration which, if more melancholy, is not less great, on account of the injuries or disease which they inflict as parasites or pathogenic agents upon man, beast, or plant. The importance of the lower organisms from the practical standpoint has already been the cause of specialisation in their study. An instance of this is seen in the rise

and rapid growth of the science of bacteriology, and the special study of yeasts and fermentation has been dignified by the name of zymotechnology. By "Protistenkunde" or protistology is denoted a wider field of study, embracing all Protista as its objects, and of which bacteriology and kindred sciences are but subordinate branches.

It is not surprising, therefore, that a journal has appeared which is to be devoted entirely to protistology. The *Archiv für Protistenkunde* will be welcomed by a wide circle of naturalists, and will find a place in every biological library. Edited by Dr. Fritz Schaudinn, who has himself pursued the study of Protozoa with such remarkable success, its high standard of excellence is practically guaranteed. The contents of the first number do not disappoint our expectations, while they show at the same time that the aim of the journal is to be scientific rather than practical. With contributions headed by names so well known as Hertwig, Bütschli, Brandt and others, the new journal makes a good start.

The first article is contributed by Prof. R. Hertwig, and is a very interesting discussion on Protozoa in relation to the cell-theory. To show the scope of his dissertation, it must suffice to quote his principal conclusions. He attempts "to develop a uniform conception of the cell, applicable alike to Protozoa and Metazoa," recognising that any such attempt does not rest at present on a very firm basis, but thinking it nevertheless more useful to formulate precise conclusions, which can be criticised, than to rest content with vague indications.

"Three kinds of substances, characterised by the part they play in cell-life, must be assumed : (1) the achromatic substance ; (2) the chromatin ; (3) the nucleolar substance. These three substances show the following distribution in the cell of the Metazoa, and probably also in that of multicellular plants. The protoplasmic framework—leaving out of consideration the material filling the meshes or alveoli (Bütschli)—represents an intimate union of achromatic framework and chromatin, of which the latter is only separated out under special circumstances in small quantities, and then induces a heightened staining-capacity of the cell body. . . . The linin-framework of the nucleus consists only of achromatic substance, in which is deposited the chromatin, bound up with nucleolar substance and thereby organised. In this way arises the chromatic nuclear framework of authors. An excess of nucleolar substance forms the true nucleoli, which in the majority of cases are subsequently used up in the formation of chromosomes in karyokinesis, in the Metazoa just as in *Actinosphaerium*."

The first number contains five other articles besides that of Hertwig, amongst which may be noticed one by Bütschli on the structure of the Cyanophyceæ and Bacteriaceæ, a monograph of the Coccolithophoridæ by Lohmann, and a discussion by Doflein of the outlines of classification of the Protozoa. The last-named author divides the Protozoa into two main divisions : first the Plasmodroma, characterised by possessing organelles for locomotion

"which can be easily recognised as protruded portions of the body-protoplasm, and which, moreover, in many cases can be extruded and withdrawn as required" ;

secondly the Ciliophora, in which the organs of locomotion, when present, are cilia. The Plasmodroma comprise the three classes Rhizopoda, Mastigophora and Sporozoa ; the Ciliophora comprise the Ciliata and Suctoria.

In conclusion, it is only necessary to add that the various memoirs are illustrated, where necessary, by lithographed plates of the degree of excellence to which one is accustomed in German zoological periodicals.

E. A. M.

AN ASSAYER'S HANDBOOK.

Assaying and Metallurgical Analysis for the use of Students, Chemists and Assayers. By E. L. Rhead and Prof. A. Humboldt Sexton, F.I.C., F.C.S. Pp. x + 431. (London : Longmans, Green and Co.) Price 10*s.* 6*d.* net.

THE differences between assaying and chemical analysis in the ordinary usage of the terms are perhaps not very precise. An effort was made some years back in America to apply the word "assaying" only to the estimation of some or all of the elements in a substance by means of dry reagents and heat, and the word "analysis" to all estimations by the use of reagents in aqueous solution. These definitions, however, have not met with much favour, and have little to recommend them. It would be better to limit "assaying" to the estimation of the valuable constituent or constituents of an ore or other substance, and to use "analysis" for the estimation of the other constituents and for all qualitative determinations. According to this view, a gold ore would be assayed for gold and silver, and the sulphur, copper, iron, &c., would be determined by analysis, while a copper ore would be assayed for copper, the sulphur in iron pyrites would be determined by assay, and so on. Messrs. Rhead and Sexton have in general followed this method, but there are difficulties in its adoption, and in any case an authoritative definition is required.

There are already many books on the subject, and although some of them are out of date, the need of a new one which does not follow any strikingly original and advantageous plan does not seem pressing. It may be presumed that the authors of the book under review have found difficulties in teaching their students with the aid of the older books, and after supplying their own wants have decided to offer their system to other teachers. The result is by no means displeasing. The plan of the book is excellent. The student or assayer can find what he wants without delay, and the description of the required process is always terse, usually accurate and in many instances sufficiently complete. The accuracy, however, is unfortunately by no means without exception, but the chief fault of the book is that in the effort to reduce its size terseness has been pushed to an extreme, and the working directions are often insufficient to enable the process in course of description to be properly carried out even by an assayer of some experience unless he has been previously taught what to do.

An example of the lack of accuracy occurs in the description of the iodide method of estimating copper, in the course of which on p. 79 the student is informed that

"Cupric salts liberate iodine from potassium iodide. The liberated iodine may be estimated by means of a solution of potassium thiosulphate of known strength, sodium iodide and sodium tetrathionate being produced."

If he is puzzled by the production of sodium salts from potassium thiosulphate, and turns to the fuller account on p. 85 for elucidation, he is confronted by the equation

$$2CuSO_4+4K=Cu_2I_2+2K_2SO_4+2I.$$

In the subsequent directions, moreover, no attempt is made to shorten calculation by the use of a normal standard solution or of one that will enable the percentage of copper to be read off from the burette. The student is told to "Dissolve [0·5 grm. copper] in 5 c.c. nitric acid and boil till all nitrous fumes are expelled," a dangerous piece of advice, and one that contains no hint of the practice now often preferred of getting rid of the nitric acid by means of sulphuric acid and so removing all chance of the disconcerting return of the blue colour. The dangers of terseness are also shown in the account of the estimation of lead as lead sulphate, on p. 64, where the directions are as follows:—

"The solution is evaporated with sulphuric acid till the fumes of the acid are given off. The solution is diluted with water, allowed to settle, filtered, washed by decantation with water acidulated with sulphuric acid, and finally on the filter with dilute alcohol or water," and so forth.

These directions are inadequate, and it may be doubted whether either Prof. Rhead's or Prof. Sexton's students have ever been set to work without a fuller and more careful account of the precautions to be observed.

Among other blemishes, the omission of all reference to Mulder's neutral point in the Gay-Lussac method of estimating silver may be mentioned, and the importance of check assays in this method is not sufficiently insisted on.

However, all these faults do not prevent the book from being useful both as a supplement to oral laboratory teaching and as a book of reference to experienced assayers. It is divided into three parts, part i. being devoted to a brief description of laboratory appliances and general processes, part ii. to the assay of the more important metals as well as chlorine and sulphur, and part iii. to a short account of certain analyses which have to be made in practice in metallurgical works. Of these, part iii. is perhaps less satisfactory than the others, but, although it is far from complete, there is much useful information in it, and speaking generally, analytical chemists and assayers will not regret the addition of the volume to their bookshelves. T. K. R.

OUR BOOK SHELF.

The Climates and Baths of Great Britain. Vol. ii. Pp. xvi + 628. (London: Macmillan and Co., Ltd., 1902.) Price 12*s.* 6*d.* net.

THIS volume completes the work undertaken by the committee of the Royal Medical and Chirurgical Society of London in 1889. The general arrangement of the subject-matter is on the same plan as in vol. i., and in order to maintain this uniformity the meteorology of the same series of years (namely, 1880–1890) has been investigated.

The volume deals with London and Middlesex, the east coast, the midland counties, Lancashire, the lake district, Northumberland, North and South Wales, Ireland—including its mineral springs; and the whole of the work has been placed in the hands of contributors whose names are well known in the medical world. It should be added that seven excellent maps, showing areas, elevations, rainfalls and isothermals, are also incorporated.

The local information contained in this and in the former volume was mainly collected by means of circular letters sent to medical men practising at the various health resorts and bath-places, in which they were asked their opinion as to the prevalence of certain diseases; the influence of the climate upon patients sent there for the treatment of different diseases; the common causes of death and frequency of old age among residents; the system of drainage; the water supply; and the local climatological data. Where medicinal baths exist, inquiry was made as to what morbid conditions are treated with advantage by these baths, the ways in which the waters are employed, the diseased conditions contraindicating their use, and the time of the year advised for their application.

The chapter dealing with London and Middlesex is certainly one of the best. The writer, Dr. William Ewart, remarks that in London "everything is artificial," from the "made ground" upon which it is built to its water courses, some of which are turned away from their natural beds, and to the composition of its air, so much altered by smoke, London fogs and mists, that the meteorology of London is one *sui generis.* Dr. Ewart asks, why should life in London be, on the test of mortality, so much safer than in many other districts? This he considers to be partly explained by the relative dryness and warmth prevailing in the streets; and he concludes that, with all its faults, its climate is a protective one, with less exposure, greater warmth and less humidity than is the case in many other districts.

The work is undoubtedly a valuable one, and well repays the large amount of time and labour which must have been devoted to its compilation. It will be found alike serviceable for reference to medical practitioners and their patients, and also to medical officers of health and local sanitary authorities, who are so largely interested in the health of the communities under their charge. The only respect in which this useful work leaves something to be desired is that the information should be of a more definite character than that furnished with reference to the prevalence of disease in some of the localities dealt with.

Electric Wiring: a Primer for the Use of Wiremen and Students. By W. C. Clinton, B.Sc. Pp. viii + 179. (London: John Murray, 1902.) Price 1*s.* 6*d.*

ELECTRIC wiring is not a very suitable subject on which to write a primer. From the wireman's point of view it is a subject to be studied only by practical apprenticeship; from the engineer's it is a special branch of electrical work to be taken up at a time when primers are things of the past. Nor do we quite see the right of such a book to a place in Mr. Murray's "Home and School Library," which is intended (as an advertisement sets forth) for the general reader as well as for school use. The general reader does not want to know how to make joints, and the schoolboy would be far better employed learning the first principles of electricity instead of the elementary details of one of its practical applications. Apart from considerations such as these, it must be admitted that Mr. Clinton has done his work well and written an interesting little book. He deals with wiring for both electric light and electric bells, and as these between them involve the principles of electricity, magnetism and electrochemistry, he has said a few words about the theory of all three subjects, and has strengthened these by the addition of some worked examples of an elementary character. The theoretical parts are necessarily brief, the bulk of the book being devoted to descriptions of the practical

work which are clearly written and well illustrated. A little more space might have been given to the construction of bell indicators and to the maintenance and peculiarities of batteries, both of more importance to the wireman than the details of the manufacture of electric incandescent lamps. Also the distribution of lamps to give the best illumination, the use of globes and shades, and the ageing of incandescent lamps are all subjects on which wiremen would be wise to be informed, which are dealt with either inadequately or not at all. There is a question we should like to ask: Is Mr. Clinton correct in saying that the B.C. holder is known as the "bottom contact"? We had always thought that the letters stood for "bayonet cap," and certainly "bayonet holder" is much the more general phrase.

Finally, we may add that the book should be useful to the wireman entering for the City and Guilds examination in this subject; he will find it a valuable travelling companion as he proceeds to the examination room.

M. S.

The Common Spiders of the United States. By James H. Emerton. Pp. xviii + 225. (Boston, U.S.A., and London: Ginn and Company, 1902.) Price 6*s*. 6*d*. net.

THE study of spiders is probably less neglected in the United States than in Britain, for writers on general entomology like Packard and Comstock have included them in their works, and there are several valuable books on the subject. Still, spiders are less popular than butterflies or beetles, and Mr. Emerton has brought out the work before us, illustrated with no less than 501 illustrations in the text, in which he has given a very useful account of the commoner American spiders, classed under ten families. Mr. Emerton informs us that there are at least 300 or 400 species of spiders to be found in the neighbourhood of any city in the United States. The introductory matter is very good, dealing with structure, habits, collecting, &c., and the diagrams on p. ix, showing the undersurface of a spider and the front of the head, are particularly clear. So many families, genera, and occasionally even species of spiders are common to the United States and Europe that a student beginning to collect British spiders could not do better than use this book in conjunction with Miss Staveley's "British Spiders," before passing on to the more elaborate works of Blackwall and Pickard Cambridge.

Trees in Prose and Poetry. Compiled by Gertrude L. Stone and M. Grace Fickett, Instructors in State Normal School, Gorham, Maine. Pp. xi + 184; illustrated. (Boston, U.S.A., and London: Ginn and Company, 1902.) Price 2*s*.

THERE are many methods of nature-study in America, and in some more attention is given to the æsthetic and emotional sides of education than to the scientific. This little book is a collection of extracts from good writers showing that trees have often been the source of literary inspiration. It is good that children should become familiar with the best literature their country provides, and when at the same time they have their attention directed to the study of nature, the lesson becomes of increased value.

Chart of the Metric System. Constructed by Prof. C. Bopp. With a pamphlet of "Notes." Pp. 15. (London: Williams and Norgate.)

THIS diagram of the metric units of length, area and volume is printed on a sheet of paper about 3 feet 6 inches by 2 feet 6 inches. The various measures are shown full size. To be of the greatest use in class teaching, the chart should be used in conjunction with models, and fortunately these are to be obtained. With the aid of the "Notes," teachers should have no difficulty in making the idea of the decimal system easy of comprehension to their pupils.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Vortex Spirals.

IT appears that a reference to Dr. W. M. Hicks's memoir on the properties of spiral fluid vortices (*Phil. Trans.*, 1898), inserted in the recent reprint of FitzGerald's Helmholtz lecture of January, 1896 ("Collected Scientific Writings," p. 353), has suggested the misconception that the idea of spiral vortices originated with FitzGerald and was subsequently developed by Hicks.

It is beyond doubt, from the context, that FitzGerald derived his knowledge of the possible existence and the properties of vortex spirals from the detailed discussion of vortex theories of matter and their difficulties, contained in Dr. Hicks's presidential address to Section A of the British Association in September, 1895; in this address, and in papers communicated to Section A, that striking extension of vortex theory was explained in illustration of the structure of optically rotational atoms. This is the more certain as Dr. Hicks's observations (*loc. cit.*) as to the possibility of the mutual absorption of a pair of Hill's spherical vortices (M. J. M. Hill, *Phil. Trans.*, 1894) were mentioned by FitzGerald in the same context.

Bipedal Locomotion in Lizards.

THE accounts of bipedal locomotion among lizards contributed by Mr. E. A. Green and Miss R. Haig Thomas are of high interest. This peculiar method of progression has been recorded by me of the Australian lizards *Physignathus Leseuri* and *Amphibolurus muricatus*, in addition to the frilled species *Chlamydosaurus Kingi*, all belonging to the Agamidæ. More recently I have found by experiment that a member of the American greaved lizards, *Tupinambis nigropunctatus*, possesses a like bipedal habit, and have been informed by a correspondent, Mr. H. Preston, that the same locomotive peculiarity is commonly manifested by the allied form *Amiaeva Surinamensis* and also by sundry species of the typical iguanas. Another correspondent has informed me that that singular iguanoid the basalisk is likewise bipedal, not only on *terra firma*, but that it will also run rapidly over the surface of water in an erect position. As is the case with the long-toed aquatic birds the jacanas, the feet of the running lizard are most probably in this case supported in transit by a more or less substantial substratum of water plants.

The bipedal progression attributed to *Lacerta viridis* and an allied form is, as compared with that of the above-named species, relatively incomplete; the tail is not raised clear from the ground during locomotion, and neither is the erect attitude sustained for any duration of time. The conspicuously greater length of the hind limbs that characterises all those species of which sustained bipedal locomotion has been recorded is a prominent feature in many other types which will probably be found to possess the same habit. Among these, members of the agamoid genera Goniocephalus, Otocryptis, Japalura and Calotes[1]; some of the Anolids, Uraniscodon and others among the Iguanidæ, and Cnemidophorus belonging to the Teiidæ, may be indicated as likely to yield affirmative evidence in this direction.

Theories of Heredity.

IS there not room for some provisional hypothesis which shall include both Galton's and Mendel's ideas, which are not necessarily antagonistic, but may turn out to be as simultaneously true as the laws of Boyle and Charles, so that the final results may be of the nature of a product or resultant? I mean that instead of drawing a hard-and-fast line between "recessive" and "dominant" characters we may suppose that these differ like heat and cold, in degree but not in kind. So that "*dominance*" *may be measured on some scale from* 0 *upwards, the measure of dominance being perhaps a function of the number of generations for which a character has been established.*

[1] Since writing this letter, a confirmation of my anticipation in the case of this genus has been recorded in NATURE for October 9 by Mr. N. Annandale.—W. S-K.

To take an instance. Last year (1901) I carefully hybridised two varieties of the sweet pea, using lens, paint brush and muslin nets. One variety used was "Gorgeous," of a salmon-orange colour. It is described in Burpee's catalogue as an improved "Meteor," and "Meteor" was brought out by Eckford about 1893. The other variety was a new cream white, Eckford's "Mrs. Kenyon," novelty of 1901.

The seeds formed were some pale and some dark, the colour following that of the mother parent. None of the flowers of the offspring have been cream-coloured; the seeds borne on "Mrs. Kenyon" by pollen from "Gorgeous" have all yielded purple flowers unlike either immediate parents, but probably taking their colour from the known remote purple ancestor of our sweet peas. Of seeds borne on "Gorgeous" by pollen from "Mrs. Kenyon," eight plants yielded flowers like "Gorgeous," but ten of the plants yielded purple flowers.

Here the dominant purple appears to be due to the previous long ancestry; the salmon variety of ten years' standing has several representatives, but not one single cream flower stands for the 1901 novelty. HUGH RICHARDSON.

Bootham School, York.

The Fertilisation of Linum.

IN the *Proceedings* of the Academy of Natural Sciences of Philadelphia for 1902, pp. 33–36, is a very interesting paper by the late Mr. Thomas Meehan, treating of some points in the life-history of certain plants. On p. 36, Mr. Meehan says:—"Mr. Darwin once stated that one might as well use organic dust as to endeavour to get seeds of *Linum perenne* by the aid of its own pollen. I found *Linum perenne* of our Rocky Mountains abundantly fertile with own-pollen, and said so in one of my papers." As some anti-Darwinian will probably make much of this statement, it is as well to say that the Rocky Mountain plant is a distinct species, *Linum lewisii*, Pursh.

In the same paper, Mr. Meehan has some very interesting remarks on the fertilisation of Lobelia, and shows that the Bartram Oak, *Quercus heterophylla*, Michaux, is not a hybrid, but a mutation (quite of the DeVriesian sort) of the pin oak. It will therefore be called *Quercus palustris heterophylla*. Mr. Meehan attributes such variations to "varying degrees of vital energy," and supports this view by calling attention to the fact that in the ivy, for instance, the leaves may at first be more or less lobed, but become wholly entire later on, in the same individual plant. One also recalls the great difference between the early and late leaves of many Malvaceæ, and of species of Eucalyptus. It is to be remarked, however, that these differences occur in a regular manner, and their order cannot be reversed. T. D. A. COCKERELL.

East Las Vegas, New Mexico, U.S.A., October 7.

Retention of Leaves by Deciduous Trees.

HAVING followed the interesting discussion relating to the deferred shedding of their leaves by young beeches, it seems to me that something yet remains to be said, though, as I take it, P. T. (NATURE, May 15) has come very close to the solution. The phenomenon is common here also, and much more of the same kind can be seen. The maturing of leaves appears to be retarded by two causes. In older trees the lower branches with their leaves come late to maturity by reason of the tendency of the energy of growth to expend itself toward the higher branches. With young trees, and especially such as are cultivated late in the season, maturity of the fresh growth is slow by reason of excess of vegetative activity. In both there is failure to mature the abscission layer of cork at the base of the petiole and consequent retention of the leaves. In seasons of early autumnal frosts, the late-growing and imperfectly lignified parts of trees are the first to suffer. D. T. SMITH.

Louisville, September 25.

THE SCOTTISH ANTARCTIC EXPEDITION.

THE Antarctic summer of 1902-3 will see the unprecedented number of five exploring steamers at work on the edge of the southern ice, and three of these under the British flag. The fifth expedition is on the point of departure, and it promises to be by no means the least important, its equipment for some branches of research being remarkably complete. An objection may perhaps be taken to the name given to this expedition—the Scottish National—for, so far as we are aware, no public body or learned society in Scotland has been asked to accept any responsibility and none has claimed any credit in the matter; we fear, too, that the number of subscribers is not great enough to indicate any widespread interest amongst the people of Scotland. To Mr. W. S. Bruce is due the whole credit of planning the expedition, arranging all details of equipment and organisation, and beating up subscriptions with a pertinacity which has deserved and commanded success. He now goes out as leader of the expedition, his enthusiasm in all branches of science and his unequalled experience of work in the ice of both Polar zones justifying hopes of good results. In a very full measure it is Mr. Bruce's expedition. Next to him, honour is due to the small number of munificent subscribers, all, we believe, Scotsmen, whose generosity has made the enterprise possible. The expedition is in truth Scottish throughout, but without the formal recognition and support of the leading learned societies it cannot rightly be considered national.

In a paper read to the British Association at the recent meeting in Belfast, Mr. Bruce gave details of his plans and equipment, and on this authoritative statement we base the following remarks.

While the British national expedition on the *Discovery* and the German national expedition on the *Gauss* are devoting attention in the first place to magnetism, for the study of which the ships were specially designed, and the Swedish expedition in the *Antarctic* is in large measure geological, the Scottish expedition will be mainly devoted to oceanography and meteorology. Other branches of science will, of course, be attended to in each case, and Mr. Bruce has made ample provision for turning all opportunities to account.

The ship for the expedition was an old Norwegian whaler, the *Hekla*, which might possibly have made a Polar voyage in her original state; but, on examination, it was found desirable practically to reconstruct her so as to render her absolutely safe in any circumstances that can be foreseen. She was accordingly stripped of her outer skins and resheathed, fitted with new masts and spars, and her whole internal arrangements and deck-plan remodelled, from the designs of Mr. G. L. Watson, by the Ailsa Shipbuilding Company at Troon. Her name suffered a similar sea-change, and she is now the *Scotia*. A vessel of about 400 tons, she is 140 feet long with 29 feet beam, and draws 15 feet of water. She has graceful lines, is barque-rigged, and is fitted with a new engine and boiler which have proved able to propel her at the rate of eight knots, while she is confidently expected to prove a fast sailer.

The leader, captain and scientific staff will occupy an after deckhouse, the officers will be berthed amidships and the crew forward. A large deckhouse has been built amidships containing the galley and also a large, well-lighted laboratory, where most of the scientific work will be carried on. It communicates with a zoological laboratory on the deck below, adjoining which there is a photographic dark-room. This lower deck contains two great drums each carrying 6000 fathoms of cable (presumably of steel wire, as each drum weighs six tons), which is led up to a 40-horse-power steam winch on the upper deck, and is to be used for trawling and trapping in the deep sea. Ample sounding wire is also carried. On the after deck, a special petrol engine is employed for working the winch for winding in the great meteorological kite specially designed and constructed by Mr. John Anderson, of Edinburgh, but of which no description has yet, so far as we are aware, been published. A full equipment of meteorological and oceanographical instruments of the best patterns has been provided.

The expedition has been fortunate in securing the services of Mr. Thomas Robertson, of Peterhead, as

captain of the *Scotia.* Captain Robertson has been engaged in Arctic whaling for twenty years, and has made some interesting geographical surveys on the coast of Greenland. In 1892, he took part with the Dundee whaling fleet in an Antarctic voyage, and he is not likely to neglect any opportunity of exploration in the far south. While the captain is in command of the ship, the command of the expedition is in the hands of Mr. Bruce alone, and he is responsible for the plan, which he is free to vary as circumstances may require or suggest, and for the direction of all the scientific work. Mr. Bruce will be supported by a scientific staff of six, including Mr. R. N. Rudmose Brown (son of the late Mr. Robert Brown), as botanist and observer of plankton; Mr. R. C. Mossman, as meteorologist, a choice which ensures the highest efficiency in that department; and Dr. J. H. H. Pirie, as medical officer and geologist. Dr. Pirie has studied oceanic deposits with Sir John Murray and has also had experience of field-work in geology. The zoological work will be shared between Mr. Bruce himself and Mr. Wilton, an old companion on the Jackson-Harmsworth expedition. Two younger men will also go as assistants.

The plan of the expedition is stated to be as follows:— The *Scotia* is to proceed direct to the South Atlantic Ocean, and in the coming Antarctic summer she will go "as far south as is compatible with the attainment of the best results to science." The Scottish station is marked on the map accompanying Mr. Bruce's Belfast paper as in 82° S., 30° W.; but it is explicitly stated that the ship will, if possible, be kept clear of the ice and will not winter in the far south unless that course cannot be avoided. Hence we doubt whether a latitude within many degrees of that designated can be reached. The Antarctic winter of 1903 is to be spent in oceanographical work to the north of the ice-pack, an arduous programme, but one likely to secure very interesting results if the sea is not too rough for working the instruments. If funds permit, a second trip into high latitudes will be made in the following summer. We consider it is extremely important that this should be done. After providing one of the finest Polar ships afloat at great expense and bringing together a singularly competent staff of specialists, it would be most unfortunate not to utilise the opportunity for securing two years' work. In the interests of science we would appeal to those who are generously bearing the cost of this expedition to do a little more, to free Mr. Bruce absolutely from any further anxiety as to expense and leave him no excuse for not reaping fully the harvest of scientific results which lies awaiting him in the field he has succeeded at last in entering.

THE NATURAL HISTORY OF THE THAMES VALLEY.[1]

IN a series of pleasantly written and beautifully illustrated articles, a large proportion of which have previously appeared in various serials, such as the *Spectator*, *Country Life*, and the *Badminton Magazine*, Mr. Cornish introduces his readers to a number of interesting facts connected more or less intimately with the valley of the Thames and its tributaries. Indeed, if we may judge by a statement made in the preface, and the evidence afforded by the text itself, few Englishmen can be better acquainted, both from the natural history and the sporting point of view, with the basin of the Thames than the author. In the first chapter we are introduced to the Thames at Sinodun Hill, in the next the manner in which the great river receives its supply of water is discussed, while the shells, plants and insects of the Thames form the subject of the next three chapters.

[1] "The Naturalist on the Thames." By C. J. Cornish Pp. viii + 260; illustrated. (London: Seeley and Co., Ltd., 1902.) Price 7*s*. 6*d*.

Perhaps the author is a little too much dominated with the idea of the great antiquity of fresh water and all its belongings, but this is a small point; and his notes on the variation of colour presented by the Thames Neritina, and the remarkable manner in which these empty shells collect in vast quantities in certain parts of the river-bed are of considerable interest. Indeed, it would be well worth while for some investigator to turn his attention to the manner in which these accumulations of shells are brought together. Several chapters are devoted to fish and fishing, the chub coming in for a special share of attention, and eel-traps being fully described. The two chapters on Wittenham Wood are specially interesting, as showing the numbers of wild mammals to be met with a few years ago in the Thames valley. From the former of these chapters we select, as a sample of the illustrations of the volume, the exquisite photograph of a pair of otters herewith reproduced.

The migratory and resident birds of the district are treated of in a couple of chapters, in the first of which the author states that, as the result of several years' observation, the river serves as the migration route of several species of birds besides swallows. "Sand-martins," he writes, "when beginning the migration, travel down the Thames in small flocks, and sleep each night in different osier-beds. How many stages they make when 'going easy' down the river no one knows. But I have seen the flocks come along just before dusk, straight down stream, and then dropping into an osier-bed." A third chapter describes the birds to be seen on the reservoirs in the valley.

The plants of the Thames valley, other than those of the river itself, receive attention in two chapters, the one treating of various poisonous kinds, while the other describes the flowering species to be met with in the meadows. Nor are economic and agricultural considerations by any means neglected. In one article, for instance, the author gives notes on the different breeds of sheep to be met with in the Thames watershed, while in a second he discourses on watercress and osier-growing. Sporting readers will find much to interest them in the account of netting red deer in Richmond Park, while the lover of picturesque scenery will be delighted alike by the author's descriptions and the photographs by which they are illustrated.

In discursive and chatty writings of this description Mr. Cornish is indeed thoroughly at home, and his book ought to command a large circle of readers who delight in our chief river and its neighbourhood. But in not a few of his chapters the author attempts more ambitious subjects, where in several places he gets sadly out of his depth. For instance, on the very first page we find it gravely stated that "there are in Lake Tanganyika or the rivers of Japan exactly the same kinds of shells as in the Thames." We may take it, charitably, that by the somewhat vague term "kinds" the author means genera and not species. But even then the reference to the molluscan fauna of Tanganyika is a most astounding and unpardonable error. Has the author, we may well ask, never heard of Mr. J. E. S. Moore's famous expedition to that lake, and the shoals of papers that have been written with regard to its so-called "halolimnic" molluscan fauna? It is perfectly true, indeed, that Tanganyika, like other African lakes, contains several widespread genera, such as Planorbis and Paludina common to the Thames and other freshwaters of Europe and Asia, but in addition to these it is the home of quite a number of peculiar generic, if not family, types of molluscs unknown at the present day anywhere else in the world. And we are told that its shells are exactly the same as those of the Thames!

In describing the freshwater "limpet" (*Ancylus fluviatilis*), the author alludes to it as "shaped like a Phrygian cap." On referring to the plate of "Thames

Shells," facing p. 14, it will be seen that in place of this species the author has actually had figured the marine shell commonly known as *Pileopsis hungaricus!* Nor is this all, for in the same plate an Ampullaria does duty for Paludina (or Vivipara); while instead of the freshwater Thames Neritina we have the marine West Indian *Neritina radiata* depicted. Comment is superfluous!

Neither is Mr. Cornish less unfortunate when, in the chapter on "London's Buried Elephants," he essays to enlighten his readers on the fauna of the Thames valley in Pleistocene times. Passing over his misuse of the term "Prehistoric" as equivalent to "Pleistocene," which in a work of this nature may be regarded as a venial sin, we find on p. 234, in connection with the discovery of mammalian remains during the excavations for the foundations of the Victoria and Albert Museum at South Kensington, the following sentence:—

"So on the London 'veldt' there were lions, wild horses (perhaps striped like zebras), three kinds of rhinoceroses—two of which were just like the common black rhinoceros of Africa, though one had a woolly coat—elephants, hyænas, hippopotami, and that most typical African animal, the Cape wild dog!"

FIG. 1.—Otters.

The author may well place a note of admiration at the end of this sentence, for it is in truth a most remarkable one. To begin with, Mr. Cornish is apparently unaware that the domesticated horse, with which the Pleistocene race agrees in every particular as regards its skeleton, differs remarkably from the asses and zebras in regard to the proportionate size of the front and hind hoofs; and from this essential difference we are entitled to argue that even in Pleistocene times it was most certainly not striped, such striping as occurs on the legs of certain domesticated horses being probably due to a cross. A certain degree of obscurity veils the part of the sentence referring to the Thames rhinoceroses, but it may be confidently stated that neither was *exactly like* the living African *black* species, while the woolly-coated kind was a relative of the living *white* rhinoceros! But the most astounding statement is the one relating to the occurrence of the Cape wild, or hunting, dog in the Thames valley deposits. It is true, indeed, that the present writer has ventured to refer, provisionally, a single lower jaw from a cave in Glamorgan to the same *genus* as the animal in question, but that appears to be the only evidence of the former existence in Britain of any representative of the genus Lycaon; and we are informed by Mr. Cornish that the Cape *species* once lived in London!

But this is not all, for on p. 235 we find it stated that among the London Pleistocene fauna are included "the pika, a little steppe hare, and an extremely odd antelope now found in Thibet. This is a singularly ugly beast with a high Roman nose, and a wool almost as thick as that of a sheep when the winter coat is on. It must have been quite common in these parts, for I have had two of their horns brought to me during the last few years."

From the second sentence in this quotation it is quite clear that by the "extremely odd antelope" the author means the saiga. That animal, however, is not an inhabitant of Tibet, where it is represented by its distant cousin the chiru, with which it has evidently been confounded by the author. With reference to the statement that it was formerly common in the Thames valley, we venture to differ from the author. A frontlet has been obtained at Twickenham, and we believe one or two other specimens are known from British deposits, but these are all that have come under the observation of persons competent to decide the affinities of animals represented by fossil bones.

If the two chapters we have been compelled to criticise thus severely have been before the public previously, the repetition of such absurd mis-statements is the more unpardonable.

In his proper sphere Mr. Cornish is an entertaining and pleasant writer, and it is therefore the greater pity that he is so ill-advised as to attempt subjects of which he has no practical knowledge. R. L.

MR. BALFOUR ON TECHNICAL EDUCATION AT MANCHESTER

As announced in these columns last week, the Prime Minister opened the new Manchester School of Technology on Wednesday, October 15. For many years past, the provisions for technical education in the city of Manchester have been remarkable for their excellence, and an account of the successful efforts made by the Technical Instruction Committee of the City Council, the School Board and other educational authorities to educate Manchester citizens was given in an article published in our issue for January 31, 1901. One cause among many of the high state of development of education in Manchester is the broad view of its duties taken by the Technical Instruction Committee. On several occasions the Committee has arranged for the present principal of the school, Mr. J. H. Reynolds, to visit foreign countries to study other systems of technical instruction. In this way the Manchester educational authorities have become practically acquainted with German and American methods of education, and though they have not slavishly followed these ideas in organising their new school, they have not hesitated to adopt ideas they consider suitable for the peculiar needs of their own district. For the following extracts from Mr. Balfour's speech at the opening of the new school we are indebted to the *Times*.

Mr. Balfour said he counted it a most happy and fortunate circumstance that he had been able to take any part whatsoever in an occasion which was interesting, not merely to Manchester or merely to Lancashire, but to the whole of a country which depended in an ever-increasing degree upon its power to preserve its position as a great manufacturing centre. The building was perhaps the greatest fruit of that kind of municipal enterprise in this country, and though he would be presumptuous in saying that the brief visit he had been able to pay to it had given him any adequate or sufficient idea of all that it was capable of doing for the industries of Lancashire, still nobody could go over the building, observe its equipment, study even in the most cursory manner the care which had been devoted to it, without feeling that the corporation had set a great example worthy of the place it held in Lancashire and in Great Britain.

The great building in which they were assembled was an outward and visible sign of that awakening which had come over our people in view of the ever-changing conditions of intellectual industry. There was a time when we could flatter ourselves without any undue egotism or vanity that not only were we the first of the industrial nations, but that the rest were nowhere. That time had passed never to return again, and he was far from uttering selfish complaints at that change in the condition of the world which was absolutely inevitable, and from which they ought not to be, and in his judgment would not be, the ultimate losers. It was a profound mistake to suppose that the fact that other nations were now great producing centres was an injury pure and simple to this country. It was nothing of the kind. The growth of the wealth of the world must be a benefit to every part of the world, and all that we had to do was to see that we bore our full share in the great industrial development.

But not only was there the change in the industrial condition of the world to which he had adverted, but another change had occurred more closely connected, perhaps, with the necessity for institutions of this character. It was the change from the pre-scientific to the scientific stage of industry. When England or Great Britain first obtained its great manufacturing monopoly, it was not too much to say that the relation between science and industry was of the feeblest character. There was always, of course, the closest connection between mechanical ingenuity and invention and the great growth of our industries, but the intimate correlation between the discoveries of the laboratory and the processes of the workshop was not in existence, and it was because we had been a little slow to discover in this country how intimately speculative research is connected with manufacturing progress that we were, in some branches of our work at all events, behind our neighbours, who in this respect, although not in many others, had proved themselves more ready and more apt to learn that lesson than we had ourselves. And if anybody wanted a proof of the truth of the proposition he was laying down they had only to recall the kind of meaning which the average man attached only a few years ago to the phrase "technical instruction." In the phrase "technical instruction" there was, in the minds of the people of whom he spoke, no scientific tinge or flavour whatever, but some kind of knowledge of manual dexterity, some opportunity for learning the uses of machinery, and so forth. But the fact on which he was venturing to insist, and on which the very existence and justification of an institution like that at Manchester depended, was that henceforth and evermore there would be a closer and closer connection between the most remote and abstract scientific study of the chemist, of the physicist, of the electrician in his laboratory, and the great industries of the community of which he was a member. He wished he could be quite sure that even now, and even in the more cultivated part of the community, there was a more perfect appreciation of two capital facts which he would like to impress upon all who heard him. One was that education was, and must be, an organic whole, and that it was perfectly vain to spend vast sums upon buildings and equipments unless the student who went to those places went adequately prepared to learn the lesson they could teach. He had not the slightest intention of over-exalting or over-praising foreign nations at the expense of our own, but it must be admitted that they had grasped much more fully and much more firmly the great truth on which he was insisting—namely, that a man really to profit by the scientific training which he could get in these institutions and to be able himself to turn the learning he acquired to the purpose of original discovery, it may be of original research of his own, had to go there, not a raw product, but at all events a half-prepared human product. He should go there, not only anxious to learn, but ready to learn.

Another great truth was that, after all, the persons who were responsible for the manufactures of the country were the manufacturers. It was perfectly vain and useless to turn out highly-trained and capable servants if there were not to be employers for them when they were turned out. He did not in the least know whether in Germany, for instance, they might not have overdone the matter; he had not sufficient evidence on the point, but he was quite sure something must be very wrong when he saw the extraordinary difference in the practice of the great German and in some, at all events, of the English firms. He was speaking on a subject which he only knew at second hand to people who knew the whole thing at first hand; but, unless his information greatly erred, they would find, if they went to Germany, at all events a few years ago, and studied the equipment of one of the great German industrial concerns, electrical, chemical, optical or what not, a proportion of scientifically trained students in the German manufactory enormously in excess of anything commonly thought necessary in this country. There was not the least use in the Manchester Corporation turning out competent students if those students were not to find employment when they were turned out. With the naturally conservative instincts of our nation, the tradition of the great manufacturing establishments would rather tend to make people say that the best, the only place in which to learn was not in the lecture-room, but in the shop, not at the feet of skilled professors, but actually among the artisans who were carrying on the industry, and he did not deny there was a great deal of truth in that, and that probably we gained a great deal by our extreme anxiety to make industrial training a practical training. But he felt confident that they drove that truth too far, and that, however sound the instinct might be which lay at the bottom of it, they were working it too hard at the present time, and that, if they really did mean to turn the brains, and the muscles, and the enterprise, and the energy, and the inventive skill of their countrymen to its best purpose, it was absolutely necessary to place among the directors of industry those who had not merely that admirable and necessary practical knowledge which consisted in seeing things done from day to day by the people who had to sell the article when it was finished, but, in addition, they must give that complete scientific training which had become more the basis of our whole industrial fabric.

He did not deny that there might be dangers in that course. Every policy they adopted required watching; every policy they adopted would petrify into some stupid and pedantic rules unless they kept close to the ever-varying realities of life, and if anybody said there might be a certain danger that they would have a *quasi*-scientific and industrial orthodoxy which would stand in the way of quick development in every new discovery in mechanics or in science, he did not deny that the danger might possibly exist. The way to meet it was to remember that true theory and true practice could never be divorced without loss to both, and that the ideal for which they had to strive was not that of simply imitating the processes of those who went before, but imitating their energy, their anxiety to take the best the world had to give—the world both of practice and of theory—in the changed and ever-changing conditions of our time. Let them imitate this great quality of their forefathers, and then institutions like that school would bear all the fruit of which they were capable. They would see the marriage of science and industry far more fertile and far more productive of good, and those who had called, and not called in vain, on Manchester for this great effort of municipal liberality might feel that their labours had not been thrown away, but that they had done great things for the growth, the maintenance and the expansion of those industries on which the health and existence of the community depended.

NOTES.

THE office of Meteorological Reporter to the Government of India will become vacant in about a year by the retirement of Mr. J. Eliot, F.R.S., who has administered the office with great success for a long series of years. The selection of suitable names for consideration, with a view to the filling of the prospective vacancy after a preliminary period of training in Europe and in India, is now occupying the attention of an

advisory committee of the Royal Society, nominated at the request of the Government of India. The problem of the future administration and scientific development of the department is also under consideration by the committee, in conjunction with Mr. Eliot, who is now in England for that purpose.

A BUREAU of Government Laboratories has been established in the Philippine Islands, and arrangements are being made for erecting a large building and equipping it with modern appliances for scientific work. Investigations will be made, not only of the resources of the island, but also of tropical diseases. The laboratories will provide exceptional opportunities for scientific study in the tropics.

AT a meeting of the Cold Storage and Ice Association, to be held at the Institution of Mechanical Engineers on Wednesday, November 5, at 8 p.m., Dr. Carl Linde, of Munich, will read a paper on "The Technical Application of Liquid Air."

THE new session of the Hampstead Scientific Society will be inaugurated by a conversazione, to be held on Wednesday, October 29. Prof. Boyd Dawkins, F.R.S., will give an address on "The Forest Primeval of the Coal-measures."

THE meeting of the Geologists' Association on Friday, November 7, will be devoted to a conversazione at University College, Gower Street, W.C. Exhibits of specimens and photographs of geological interest will be on view during the evening.

AN Egyptian Medical Congress will be held at Cairo on December 19-23 under the presidency of Dr. Ibrahim Pacha Hassan. The principal object of the Congress is the study and discussion of diseases occurring in warm climates. The secretary of the English committee is Dr. W. Page May, 9 Manchester Square, London, W.

THE death is announced of Mr. Peter Brotherhood, whose invention of a new type of steam engine in 1872 made his name well known among mechanical engineers. In this type of engine, three cylinders are set at angles of 120° round a central chamber, and all three connecting rods operate upon one crank within the central chamber. Mr. Brotherhood introduced important improvements in the pumps for compressing air on board ship for use in torpedoes, and thus assisted the development of the automobile torpedo. He was also the inventor of a vertical direct-acting engine.

WITH reference to the movement which has been set on foot in Berlin to raise a fund to defray the cost of erecting a statue to the late Prof. Virchow in that city, the *British Medical Journal* states that Prof. Waldeyer, who has taken the lead in the matter, summoned a meeting for October 15. At an early date a committee will be formed in this country, with Lord Lister as chairman, to afford the friends and admirers of Virchow in the United Kingdom the opportunity of contributing to the memorial. The Berlin Medicinische Gesellschaft will hold a special memorial meeting for Virchow on October 29, and the Berlin Verein für innere Medizin has already held a special meeting in memory of Virchow and Gerhardt, when a memorial oration was deliverd by Prof. von Leyden.

THE Soufrière of St. Vincent was again in eruption on October 16. The following records are abridged from reports published in the *Times*:—*Kingstown, St. Vincent.*—The eruption has caused even greater distress in the colony than that which prevailed before. Large areas of tillage lands which were hitherto considered to be outside the volcanic zone are now buried in hot sand. The roads in the Windward district are the only regular means of communication between Georgetown and Kingstown, a distance of twenty miles, and travel is extremely difficult. *Barbados.*—Between 2 and 3 a.m. on October 16, loud reports heard from St. Vincent; at 7 a.m. inky blackness in direction of St. Vincent, air quite still; at 9.30 a.m., volcanic dust commenced falling, with very strong smell of sulphur. Dust continued to fall for several days, producing a deposit about one-eighth of an inch thick. *Windward Islands.*—Soufrière in full eruption October 16, between midnight and 5 a.m. No loss of life reported, but heavy fall of sand and stones, principally on Windward side as far as Union; slight fall Kingstown and Leeward coast. A layer of volcanic material eight inches deep was deposited in the Carib country. *Guadeloupe.*—Loud detonations were heard, and a glimmering light was seen in the direction of Martinique in the early morning.

WE have received from Mr. P. Baracchi, Government Astronomer, the results of observations in meteorology and terrestrial magnetism made at the Melbourne Observatory and other localities in the State of Victoria for the last half of the year 1901. These periodical results form a valuable contribution to the climatology of that part of Australia, showing in a concise form the monthly means and extremes at a considerable number of stations of the second and third orders, and the monthly and yearly rainfall of all the numerous stations in the State, together with the average rainfall computed from the results of as many years as are available for the purpose. In some cases the series exceeds forty years' duration.

WE learn from the *Auto-vélo* that Captain Ferber, of Nice, has recently made some highly successful experiments in aërial gliding. His first attempts were made with a machine of the Lilienthal type, with which several glides were effected, but this machine was destroyed by a sudden gust of wind, and Captain Ferber has now adopted a form of aëroplane similar to the two-surface machine of Mr. Wilber Wright and his brother, in which the operator assumes a horizontal position and steers by means of a rudder placed in front. The newspaper states that the captain is enchanted with his apparatus and hopes to beat the record of Mr. Wright of 150 metres. He finds the machine remarkably stable and easy of manipulation, and by careful management of the rudder he is able to land without any shock.

A SECOND edition of Dr. S. P. Langley's memoir containing the results of his "Experiments in Aërodynamics" has been published by the Smithsonian Institution. The work originally appeared eleven years ago, and the principles and experiments described in it have since been used in the construction of aërodromes or flying machines. At the end of his memoir, Dr. Langley refers to the position and promise of aërial navigation in the following words:—"Since the preceding lines were written, the writer has demonstrated that mechanical flight is possible by actually performing it with steel flying machines nearly a thousand times heavier than the air, driven by steam, and employing as a rule curved sustaining surfaces. These machines, which were built by the writer, weighed from thirty to forty pounds, and they have arisen and descended in safety, their flight being limited to distances of from half a mile to three-quarters of a mile, at speeds varying from twenty to thirty miles an hour (see NATURE, vol. liv. p. 80, May 28, 1896). The 'inchoate art' of aërodynamics has since made a corresponding progress, and while leaving a great deal to be done, it is believed by the writer that the time is now very near when human beings will be transported at high velocities, though perhaps at first under exceptional conditions such as are demanded in the arts of war rather than of peace."

VERY little ice has been reported from the north-western quarter of the North Atlantic this year. The Meteorological Office pilot chart for November shows that since the beginning

of September a few large bergs have been passed on the steamer route between Belle Isle and the 50th meridian, but the strait of Belle Isle appears to have been quite free since about August 20, while no ice has been met with on the banks of Newfoundland for a long time past. For the month of September, 4300 observations of North Atlantic sea-surface temperatures were discussed, the results showing that nearly the whole of the area northward of the 48th parallel was warmer than the average, while between 30° and 48° N. there was a deficiency. In the immediate vicinity of the British coasts there was a slight defect, the air temperature over the land having been from 1° to 3° below the average. Further information relating to the West Indian volcanic eruptions is given, based on reports from captains of ships and on the preliminary report to the Royal Society by Drs. Anderson and Flett. At 2.30 a.m. on May 8, volcanic ash was falling on board the barque *Jupiter*, at a distance of 930 miles east-south-east (to windward) of St. Vincent, about twenty-four hours after the violent outburst from the Soufrière, so that the upper counter current had an average velocity of about forty miles an hour. Off Martinique, at 1.15 p.m. on August 21, the s.s. *Dahomé* was enveloped in a dust cloud from Mont Pelée, the darkness being more intense than that of night, while steam was rising from the sea in localities where the hot mud from the volcano fell into the water. Captain Leutken heard no noise or rumblings.

WE have received from Messrs. Crompton and Co., Ltd., a pamphlet describing the latest pattern of Crompton potentiometer. The advantages possessed by this instrument for accurate measurements in direct-current work are well known. It can be used to measure either P.D., current, resistance or power; the actual measurement being in all cases made by balancing two potential differences. The instrument can be at any distance from the circuit under test, the lead wires introducing no error, since, when balance is obtained, no current flows through them. The form of instrument designed by Messrs. Crompton is very compact and convenient, and enables a measurement of any kind to be made with very little trouble. The shunts and volt-boxes made to accompany the potentiometer give it a very wide range, and in its latest form provision is made for easily testing its accuracy by comparing the resistance coils with the slide wire. With this instrument, a standard cell and a galvanometer, the electrical engineer has practically al he requires for accurate testing work.

AN important memoir, by Sir George King, on the flora of the Malay Peninsula, is in course of publication in the *Journal* of the Asiatic Society of Bengal, the last fasciculus received in this country dealing with the begonias and allied groups.

THE latest issue of Gegenbaur's *Morphologisches Jahrbuch* (vol. xxx. pts. i. and ii.) contains two papers on the anatomy of mammals. In the one, Herr G. Ruge continues his account of the variations of form in the liver of the Primates, dealing in this instance with the American monkeys; in the second, Herr J. Tandler discusses the development of the cranial arteries.

THE Indian Forest Department has just issued the first fasciculus of a series of tracts dealing with insects affecting the forestry of the country under the title of "Departmental Notes." The part before us is by Mr. E. P. Stebbing, the lecturer to the school of the Department at Dehra Dun, and it is proposed in later numbers to give information with regard to both injurious and beneficial species. By this means it is hoped that the officers of the Department and others interested in forestry may be able to keep abreast of modern researches connected with the subject. Several of the insects referred to in this part are new to science. For the benefit of non-entomological readers, the descriptions might, we think, have been made a little less technical.

AMONG recent papers in the *Proceedings* of the Washington Academy is one by Prof. C. H. Eigenmann on the degenerate eyes of the blind, burrowing amphisbænian lizard *Rhineura floridina*. The case is especially interesting on account of the occurrence of a fossil representative of the same genus in the Miocene of Dakota. Unfortunately, nothing is known with regard to the eyes of the extinct form, but from the fact that all the living members of the group are blind, it seems practically certain that the degeneration of the eyes took place before the differentiation of the existing genera, in other words, at least as early as the lower Miocene. In the existing form, not only is the eye invisible externally, but there is no indication of the aperture by which it formerly opened on the surface.

DR. W. BORCHERS AND MR. L. STOCKEM describe an apparatus for the electrolytic separation of calcium from the fused chloride in the *Zeitschrift für Elektrochemie* for October 2. The separation of the alkali earth metals is one of the most difficult of electrometallurgical problems, on account of the conflicting character of some of the necessary conditions. The form of furnace used in the present experiments consists of a circular carbon box serving as anode, which is supported on, but insulated from, a cooling arrangement; a thin iron rod in the centre of the box is used as kathode, and this is connected to the cooler. The floor of the box is covered with fluor-spar, on the top of which is the layer of molten calcium chloride. This arrangement allows the temperature to be so regulated that it is above the melting point of calcium chloride, but below that of calcium. The calcium separates in spongy form and can be removed by suitable tongs; if it is pressed together before it is taken out, so as to get rid of some of the chloride, a white metallic mass containing about 90 per cent. calcium can be obtained. A somewhat similar arrangement is described for the separation of strontium. The apparatus, the authors state, is suitable for lecture experiments and also for the preparation of the metal in large quantities.

THE so-called foul brood of bees was first described under that name by Schirach in 1769, but it is supposed that so far back as Aristotle it was a recognised disease and that the remarks about it made by this writer undoubtedly refer to this particular malady. It was in 1885 that Messrs. Watson-Cheyne and Cheshire, with Koch's new bacteriological methods at their disposal, submitted this destructive disease to an elaborate scientific investigation, and shortly after presented to the scientific world a certain *Bacillus alvei* which was accepted as the *fons et origo* of the foul brood of bees. The subject has occupied much attention, not only of apiarists, but also of scientific men, and in 1900 Mr. Francis Harrison, of Ontario, published an important memoir dealing with methods of effectually combating the disease. The latest contribution to the scientific work on the subject emanates from the University of Liége, and the funds for carrying it on were provided by the Belgian Government. Dr. Lambotte, as the result of his extended researches, affirms that the *Bacillus alvei* of Cheyne and Cheshire is identical with the well-known and widely distributed *Bacillus mesentericus vulgaris*, and must be placed in the same category with, for example, the ubiquitous *B. coli communis*, which, although a normal and harmless inhabitant of the intestine, may under given conditions become pathogenic and give rise to disease. The endowment of harmless micro-organisms by suitable means with pathogenic properties is, of course, a well-recognised achievement, and Dr. Lambotte has shown experimentally how the familiar so-called potato-bacillus may artificially become invested with disease-producing powers and can engender foul-brood disease in bees.

THE Department of Revenue and Agriculture of the Government of India has recently published the seventeenth issue of

"Agricultural Statistics of India for the years 1896–97 to 1900–01." The numerical data have been compiled under the supervision of the Director-General of Statistics and are issued in two parts, the first dealing with British India and the second with native States. The information is tabulated under fourteen headings, including, among others, tables showing the total area of districts; the amount of cultivated and culturable land; the gross cultivated area under each crop; agricultural stock; the principal varieties of tenure held direct from the Government; the progress made in the production of tea and of coffee; and the average yield per acre of the principal crops. The tables are accompanied by numerous short, explanatory notes which are often of an interesting nature. The following statistics referring to the cultivation and production of indigo in British India during the past few years show that a remarkable decline has occurred, doubtless in consequence of the competition of the artificial product:—

Year.	Acres under cultivation.	Production in cwts.
1897–1898	1,339,099	166,812
1898–1899	1,010,318	139,320
1899–1900	1,026,900	111,890
1900–1901	990,375	148,029
1901–1902	803,697	121,475

AN important addition to the literature of the Myxomycetes will be found in the "Monograph of the Acrasieæ," by Mr. E. W. Olive. The paper, which is published in the *Proceedings* of the Boston Society of Natural History, provides a critical summary of the data furnished by previous writers and the results of the author's investigations. Mr. Olive follows Zopf in uniting the groups of the Labyrinthulæ and Acrasieæ under the title of the Sorophoreæ, which are related to, but more primitive than, the true Myxomycetes.

A NEW edition of the first volume of Mr. William Scott Taggart's "Cotton Spinning" has been published by Messrs. Macmillan and Co., Ltd. The book deals with all processes in cotton spinning up to the end of carding.

THE lecture arrangements at the London Institution, Finsbury Circus, for the session 1902–3, have now been announced. The list includes lectures by Lord Avebury, on "The Scenery of England and the Causes to which it is Due"; by Sir Robert Ball, F.R.S., on "The Earth's Beginning"; by Dr. A. Smith Woodward, F.R.S., on "Some newly discovered Extinct Animals"; by Prof. S. P. Thompson, F.R.S., on "The Magic Mirror"; by the Rev. W. H. Dallinger, F.R.S., on "Recent Studies in the Lives of Spiders"; and by Dr. W. Hampson, on "Liquid Air." The lectures are held on Monday evenings at 5 o'clock and on Thursday evenings at 6 o'clock.

MESSRS. MACMILLAN AND CO., LTD., have published a small collection of mathematical tables for ready reference compiled by Mr. Frank Castle and printed on stout paper. The booklet costs 2*d.*, and contains useful numbers and formulæ, tables of logarithms and anti-logarithms, as in similar tables published by the Board of Education, together with tables of natural sines and tangents for every five minutes of arc. In view of the encouragement now being increasingly given to the use of logarithmic and trigonometric tables at an early stage of mathematical instruction in schools and colleges, the collection should prove of use to teachers and students alike.

AN elaborate catalogue of balances and weights, containing more than one hundred pages and two hundred illustrations, has been published by Messrs. F. E. Becker and Co., of Hatton Wall, London. Balances and weights suitable for scientific work of every kind are described in the catalogue, and the prices at which they can be obtained are remarkably low in comparison with those of a few years ago. The quantitative work now carried on in the physical and chemical laboratories of schools has greatly increased the demand for students' balances sensitive to a milligramme or two, no less than six thousand of such balances having been introduced lately into Irish elementary schools. It is impossible to over-estimate the educational value of practice in the use of accurate balances, and by producing such instruments at reasonable prices firms like Messrs. Becker and Co. have done much to facilitate the introduction of such work into the school course.

THE existence of a pentafluoride of iodine was indicated by Gore and by MacIvor thirty years ago. On account of its bearing on the question of the valency of iodine, a further examination of the behaviour of this fluoride seemed desirable, and in the current number of the *Comptes rendus* M. Henri Moissan gives an account of its preparation and properties. The compound is obtained without difficulty in a perfectly pure state by the action of fluorine upon solid iodine, and forms a colourless liquid, solidifying at 8° C. and boiling without change at 97° C. Analyses show that the fluoride has undoubtedly the composition IF_5, and it is noteworthy that it can be distilled in a current of hydrogen without any reaction taking place. This fluoride possesses very great chemical activity; most elementary bodies decompose it, and it produces with compound bodies a large number of double decompositions. Iodine pentafluoride is decomposed at about 500° C., iodine being formed, and possibly a new fluoride of iodine.

IN the current number of the *Zeitschrift für physikalische Chemie* is an interesting paper by Mr. A. A. Blanchard on the decomposition of ammonium nitrite in aqueous solution by which reaction nitrogen is liberated. It is found that this decomposition only takes place with sufficient rapidity to enable the velocity to be determined under the influence of hydrogen ions or free nitrous acid. In these circumstances, the velocity with which nitrogen is evolved is proportional to the concentration of the ammonium ions and of the nitrite ions, being increased by the presence of other ammonium salts or nitrites, and the hydrogen ions have an accelerating effect on the reaction.

IT has been known for some time that the compounds which the albuminoids form with acids and bases are of true salt-like character. The aqueous solutions of these compounds are conductors of electricity, and presumably, therefore, contain electrically charged ions. In the current number of the *Zeitschrift für physikalische Chemie*, Dr. Sackur gives an account of experiments which he has made on aqueous solutions of casein sodium. From the variation of the conductivity with the dilution, the author concludes that casein is a tetrabasic acid with a molecular weight equal to 4540. Experiments on the diffusibility of casein sodium indicate that, although an electrolyte, it is incapable of passing through parchment paper, and in this respect therefore behaves as a colloid.

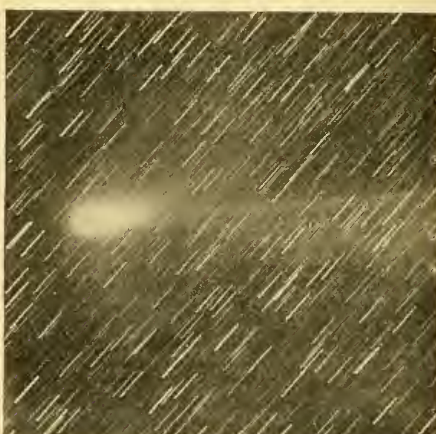
IN the *Journal* of the Chemical Society, Messrs. Chapman and Lidbury give an account of some interesting experiments on the decomposition of water vapour by the electric spark. A series of electric sparks was allowed to pass between two platinum wires sealed into a glass tube through which a current of water vapour was drawn. The gases from the anode and kathode sections of the tube were collected separately. As a result of the examination of the gases thus collected, the authors conclude that the separation of the constituent elements of water from water vapour is not entirely due to a process of electrolysis. If it were, hydrogen should appear at one electrode and oxygen at the other, whereas hydrogen collects at both electrodes. The quantities of the separated gases should, moreover, not exceed those of the oxygen and hydrogen, which collect in a voltameter

placed in the same electrical circuit, whereas the experiments show that under certain conditions the quantity of hydrogen from the water vapour which collects at the kathode is five or six times as large as that which separates in the voltameter.

The additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by Captain R. Bolton; a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mr. F. G. Lloyd; a Getulian Ground Squirrel (*Xerus getulus*) from Morocco, presented by Mr. Arthur Gill; a Cape Hyrax (*Hyrax capensis*) from South Africa, presented by Mr. A. C. Boddam Whetham; two Egyptian Jerboas (*Dipus oegyptius*) from North Africa, presented by Mr. G. Swales; a Spotted Eagle Owl (*Bubo maculosus*) from Africa, presented by Mr. C. H. Turner; a Horned Capuchin (*Cebus apella*), a Tayra (*Galictis barbara*) from South America, a Jelerang Squirel (*Sciurus bicolor*), a Larger Racket-tailed Drongo (*Dissemurus paradiseus*), two White-throated Ground Thrushes (*Geocichla cyanonotis*), an Indian Pitta (*Pitta brachyura*), an Indian Dial-bird (*Copsychus saularis*) from India, a Common Rat Kangaroo (*Potorus tridactylus*) from Australia, a Common Water-Buck (*Cobus ellipsiprymnus*) from South Africa, four Flat-backed Tortoises (*Testudo platynota*), a Phayre's Trionyx (*Trionyx phayrii*) from Burmah, two Eroded Cinixys (*Cinixys erosa*) from West Africa, two Bell's Cinixys (*Cinixys belliana*) from Tropical Africa, three Pennsylvanian Mud Terrapins (*Cinosternum pennsylvanicum*) from North America, deposited; an Amherst's Pheasant (*Thaumalea amherstioe*) from China, purchased.

OUR ASTRONOMICAL COLUMN.

Comet *b*, 1902 (Perrine).—The photograph of this comet which accompanies this note was secured by Dr. Isaac Roberts on the evening of October 10. It was taken with his 20-inch reflector and received less than one hour's exposure, namely, 52 minutes. A great amount of detail is shown on the original positive from which this reproduction has been made, and it



will be noticed that the comet has a multiple tail, two of comparatively large dimensions and several smaller streamers.

The rapidity with which the comet is travelling relatively to the stars can be gathered from the length of the star trails on the plate, the observer correcting the telescope for the comet's motion at short intervals.

A Bright Meteor.—Mr. W. Lascelles-Scott, of Little Ilford, Essex, states in the *Times* that at about 7.52 p.m. on October 15 he observed a bright meteor and noted the following particulars as to its path:—"General course and direction of the meteor, N.W. by N. towards S.W.; general angle of course to S.W. on horizontal plane, 30°; general length of course to S.W. about 105°; general shape of course, like an inclined and attenuated letter S; apparent diameter of meteor at *maximum*, about 1-25th of that of the moon, or 4 : 100; apparent brightness at *maximum*, about ⅛th that of the moon, or 12 : 100; colour variations, from faint yellow, through blue to purplish at finish; apparent duration, about 3·8 sec. (nearly 4 sec.); coruscation, faint tripartite at finish."

Observations of Fifty-eight Long-Period Variables.—Part ii. of vol. xxvii. of the *Annals* of the Harvard College Observatory is devoted to the observations of fifty-eight long-period variables. The methods employed in making these observations were explained in part i. of this volume in reference to a similar research with regard to circumpolar long-period variables. Most of the stars are brighter than tenth magnitude, and these have been observed with the meridian photometer; those between the tenth and thirteenth magnitudes have been observed with the photometer attached to the 15-inch equatorial.

By taking a series of comparison stars in the immediate neighbourhood, observing their magnitudes in order of brightness and their differences in magnitude, and then plotting a smooth curve having for its abscissa these approximate brightnesses, and its ordinate the photometric magnitude, a very trustworthy value has been obtained for the magnitude of each variable.

A New Algol Variable.—In No. 3820 of the *Astronomische Nachrichten*, Mr. A. Stanley Williams announces the discovery that the star B.D. + 41°·504 is a variable of the Algol type. The position of this star is R.A. = 2h. 30m. 50s., Dec. = 41° 34′·3 (1855), and its normal magnitude 9·4. At minimum the star's brightness decreases to nearly twelfth magnitude.

Owing to the various observations being interrupted by clouds and by daylight, the instant of minimum has not been finally determined, but from the observations which have been made, the following elements and ephemeris have been found:—

Minimum of 14 1902 Persei = 1902 Sept. 16, 16h. 38m. G.M.T.
+ 3d. 1h. 21m. 32s.·23 E.
= J.D. 2416009·6934 + 3d.·056623 E.

Ephemeris for every fifth minimum.

NOTES ON THE RECENT ERUPTIONS OF MONT PELÉE.

Dominica, September 24.

August 17.—A steamer passing five miles to the west of Mont Pelée met a heavy ash cloud, which rendered the day as dark as night whilst the vessel passed through it. The deck was covered with ash.

August 18 *and* 19.—News reached here of further eruptions of Mont Pelée.

August 25.—Detonations heard during the day.

August 26.—Loud detonations and sounds like growlings were heard in the afternoon and evening. To the south-west of the island there were very heavy black ash clouds like a wall with a level top. The sun set behind this cloud as though a solid mass, all rays of light being cut off. During the whole day the upper atmosphere was charged with dust, but very little fell on this island.

August 28.—In the evening there was a magnificent display of lightning from Mont Pelée, and the sky in the direction of the volcano glowed with a pinkish light. At 11 p.m., lightning

shot out from the mountain in all directions, zigzagging and flickering flashes alternating with, or being accompanied by, reddish globes, which ascended and exploded, and shot out stars and long rays. Away towards the south-west was another large focus of electric energy, which appeared to me to have a distinct relation to the volcanic electric discharges from Mont Pelée. This spot was, I reckoned, at least forty miles from the volcano, from which it bore almost west two points north. This latter electrical display was similar, but less extensive than that from Mont Pelée, and it was accompanied by curious glowing globes, which burst and shot out tongues of lightning. The most curious part of the magnificent sight, however, was that occasionally long rays of light, very like to the rays of a searchlight, shot out from the direction of Mont Pelée downwards to the secondary and distant electrical display, and on this broad ray reaching the western focus, the lightning there became more vivid, intense and extensive.

The West Indian volcanic explosions are undoubtedly due to the irruption of water into the reservoirs feeding the volcanoes. There are no large rivers or lakes that could supply water in sufficient quantity to produce the phenomena observed. Clearly, then, the sea has got in by some fissure or dislocation, and it has occurred to me that the electrical display to the west of Pelée observed on the night of August 28 was caused by a fissure in the sea bottom permitting an irruption of water into the reservoir from whence the volcano has obtained the material for its solid ejecta. Anyhow, the disastrous eruption of Pelée on the 30th—that is, two days afterwards—was accompanied by an enormous discharge of steam and hot water, much greater, indeed, than in the case in the earlier eruptions.

In the neighbourhood of the volcanoes there has been much alteration of the bottom of the Caribbean Sea. The cable-repairing ships report the depth in places to have increased by half a mile. On September 19, a telegram from the West Indian and Panama Telegraph Company stated that:—

"Unprecedented difficulties have been encountered in the endeavour to repair the interrupted cables between St. Lucia and St. Vincent and St. Lucia and Grenada. The cables appear to be buried under a layer of volcanic mud, and this, combined with the great depth of water, which can only be attributed to the alteration of the sea-bed due to the late eruptions, has rendered it difficult to raise the cable to the surface in consequence of the enormous strain. The repair of the St. Lucia—St. Vincent section, which was effected on the 16th instant after several weeks' operation, has been a very costly one, necessitating an expenditure of over thirty miles of new cable, and the fresh interruption which occurred in this section during the night of the 17th is in this new cable put down only the day before, and was evidently caused by some submarine disturbance."

Since the loss of the *Grappler* during the destruction of St. Pierre, no attempt has been made to repair the cable between Dominica and Martinique, so there is no recent authentic information concerning the disturbance of the sea bottom near to Mont Pelée; but Captain McKay, the Superintendent of the Quebec Steam Ship Co., who went south in the s.s. *Korona* on August 29, reported that "the sea between Dominica and Martinique was of a light green colour, which makes one think there was shoal water." This colour was due, doubtless, to the suspended ash which has fallen into this portion of the sea in enormous quantities from time to time, and it is to be expected that there has been a subsidence instead of an upheaval of the sea bottom to the west of Martinique.

August 30.—There were detonations in the afternoon, with slight vibrations of the earth; and at 7 p.m. there were exceedingly loud detonations and growlings, which continued at intervals until 2 a.m. on August 31. Volcanic ash began to fall at 5.30 p.m., and, as the night wore on, the fall was so great that the darkness became intense. The ash came from the east, so that evidently it was shot high into the upper strata of the atmosphere and carried to the north-east before it began to fall into the lower regions swept by the "trades." Later on, news came that the fall of ash in Guadeloupe was very heavy. In Montserrat the fall was lighter, and in Antigua it was lighter still.

August 31.—The fall of ash in Roseau (at the south-western end of the island) covered the surface to the depth of a quarter of an inch; the dust penetrated everywhere, closed drawers and presses being insufficient to keep out the finer particles.

September 1.—The atmosphere is still dust-laden, and the sun was obscured all day; it could be seen only towards the evening, when it set like a dull greenish disc. In the afternoon heavy ash clouds were drifting to the west through the Martinique Channel.

September 2.—Mr. A. Robinson, the Government Officer at the eastern side of the island, reports to me that the ash fell there on the night of August 30 to the depth of from an inch to two inches, that small trees and branches of large ones were broken down by the weight of the dust, which clung tenaciously to the leaves, branches and stems, and that the cattle were suffering from hunger, as the grass was covered and grazing was impossible.

September 3.—The mail steamer came in to-day from the south, and brought some refugees from Morne Rouge, which was destroyed by the eruption of Mont Pelée on the night of August 30. There was a French priest on board who was an eye-witness of the disaster. The following statement he made was kindly written down for me by Mr. C. A. Seignoret, the Quarantine Officer:—

"The phenomena were entirely new, and hot water and red-hot dust were the principal elements of destruction amongst the inhabitants of Morne Rouge and Carbet. Several houses were completely destroyed, while others sustained no damage."

Mr. Seignoret has also kindly interviewed one of the intelligent refugees for me, and he has furnished me with the following statement made by her:—

"Miss Carra, a respectable resident at Morne Rouge, who was an eye-witness to the eruption of Mont Pelée which occurred on August 30 last, informed me that rumbling noises were heard from the crater all day, with detonations and frequent flashes of electricity, and towards evening the mountain appeared to be a mass of flame, emitting alternately jets of hot water and red-hot ashes, which ascended into the air in the form of rockets, and as the ashes fell upon the wooden housetops, the buildings at once caught fire. A great many lives were destroyed by hot ashes and water, for numbers of persons rushed from their houses into the streets to escape from the flames, and as the ashes fell upon their faces and other exposed portions of their bodies, the skin at once became red as scarlet and peeled off, causing the parts to swell to an enormous size. In most cases, portions of the legs, arms and chest were burnt, while the clothes were intact. White persons got completely charred in the face, causing them to appear like coal-black negroes. Some of the gendarmes were found dead in fixed positions with their clothing quite sound, while others were burnt in various parts of their bodies. Water! Water! was the only cry from the wounded and dying, and in many instances death ensued immediately after their thirst was quenched."

This interesting account indicates that there was an ejection of much larger quantities of steam and hot water than occurred in the earlier eruptions. Persons who shut themselves close in their houses were nearly all saved, the hot blast passing quickly, but from other accounts I have received it appears that the heat was fearful for a brief period and that the rapid evaporation of moisture from the tissues caused a thirst that was agonising until assuaged.

About 1500 persons were killed and, according to the statements of *L'Opinion* of Fort-de-France, a greater number have suffered injuries. H. A. Alford Nicholls.

ASTRONOMY AND COSMICAL PHYSICS AT THE BRITISH ASSOCIATION.

At the Bradford meeting, in 1900, a department of astronomy was established as a subsection of Section A, in deference to a wish that had been expressed that astronomy should be better represented at the British Association. After two years' experience, it was felt that the astronomical papers that were received were scarcely enough to justify this division of Section A, and this year the subsection was strengthened by the addition of cosmical physics. On the Friday the whole section was given up to cosmical physics; on the Monday and Tuesday the subsection met separately. On all three days the room was well filled, and it was apparent that the enlarged subsection was in some ways a success. But towards the end of the meeting there was a strong expression of opinion that it is not to the advantage of the section as a whole that it should be so much subdivided, and the whole matter will have to be carefully considered before next year. Perhaps a solution of the difficulty

might be found in the division of all papers for Section A into two classes—papers that are generally intelligible and papers that are not—and in relegating the latter class only to sub-sectional meetings. It is not impossible that this might have beneficial results in more ways than one.

The address of the chairman, Prof. Schuster, has already been printed in full. His criticisms of mere routine observation raised an interesting discussion, in which the meteorologists reserved their defence.

Among the papers submitted to the subsection were several of general interest. Major S. G. Burrard, R.E., described the difficulties which are caused in the Geodetic Survey of India by the attraction of the mass of the Himalayas and the Thibet plateau, and by the existence of an underground chain of excessive density which runs across India. Contrary to the opinion that was held until a few years ago, it now seems certain that the plumb-line is deviated over the whole of India, and that all astronomical latitudes may be in error by a number of seconds of arc. The Government of India and the staff of the Survey must be congratulated on their good fortune in being confronted with problems of such interest and importance. Prof. Turner described an attempt made at Oxford to verify the suggestion put forward by Sir David Gill that the bright stars, as a whole, are rotating relatively to the fainter stars. From the Oxford astrographic catalogue plates he finds distinct evidence of such an effect, but with a sign opposite to that found by Gill in the southern hemisphere.

The feature of the meeting on September 16 was an exhibition of photographs from the Yerkes Observatory. Mr. Ritchey has made a most interesting set of pairs of photographs of star clusters, made respectively with a 2-foot reflector and with the 40-inch visual refractor fitted with a colour screen used in contact with isochromatic plates. With the latter, the densest parts of the clusters are beautifully resolved and measurable. The photographs of nebulæ made with the 2-foot are unsurpassed; and it is remarkable how, though nearly all the detail which they show *can be found* on the photographs taken at Crowborough and Daramona and Greenwich, the general effect is in some cases quite different. Mr. Percival Lowell sent three papers, one describing a scheme for sending expeditions in search of good "seeing." Mr. S. A. Saunder discussed the possibility of changes in the surface of the moon, and urged the need of cooperation in the work of describing minute detail. Mr. W. E Wilson reported failure in his search for Forbes's hypothetical extra Neptunian planet, and showed a bolometer mounted equatorially for measuring solar radiation.

Other papers read at the meetings of the subsection have already been mentioned in NATURE in the notes of mathematical and physical papers. A. R. H.

ZOOLOGY AT THE BRITISH ASSOCIATION.

ON September 11, in addition to the reports of committees, a short series of fisheries papers was taken:—

(1) Prof. McIntosh, who was prevented from being present, sent a detailed paper discussing British fisheries investigations and the international scheme, which was read in abstract to the meeting by Mr. W. S. Green, Chief Inspector of Fisheries for Ireland. He showed the necessity for improved statistics and for a careful survey of the off-shore and in-shore fishing grounds. He considered that hydrographical work occupied too prominent a position in the international scheme and that other more important points in connection with the distribution of fish have been omitted. (2) Mr. W. Garstang then read a statement as to the proposed programme for the international investigation of the North Sea, as passed at the recent meeting of delegates at Copenhagen. He stated that in his opinion all the investigations thought desirable by Prof. McIntosh and other critics were included in the Christiania scheme, and that that scheme was going to be carried out practically unchanged. He explained that the Government had had to adopt hydrography as a part of the proposed programme, although its importance in connection with English fishery interests might be doubtful. Finally, he urged the advantages of international cooperation. (3) Dr. Noel Paton, who was prevented from being present, sent a paper criticising the methods proposed in the international scheme, and throwing doubt upon the accuracy and value of results based upon such methods. Dr. Masterman, Dr. Mill and others spoke in the discussion which followed. (4) Mr. J. Stuart Thomson had a paper on the scales of fishes as an index of age.

The following were the reports of committees submitted to the Section:—

(1) "Migration of Birds," mainly the work of Mr. W. Eagle Clarke on the fieldfare and the lapwing. (2) "Naples Zoological Station," containing reports on work by Mr. E. S. Goodrich, Mr. N. Maclaren, Miss A. Vickers and Dr. R. N. Wolfenden, in addition to the usual statistics from the station. (3) "Plymouth Marine Laboratory," with a short report from Mr. H. M. Woodcock. (4) "Index Animalium." Vol. i. of this work, by Mr. Sherborn, will be issued in October. (5) "Plankton Investigation." (6) "Zoology of Sandwich Islands." (7) "Millport Marine Zoological Station." And (8) "Coral Reefs of the Indian Region." Mr. Stanley Gardiner reports considerable progress with the publication of his results.

The forenoon of September 12 was devoted to a series of papers, by Prof. Herdman and those who are helping him to work out his results, on the fauna and flora associated with the pearl oyster banks in the Gulf of Manaar. First, Prof. Herdman gave a general account, illustrated by the lantern, of his recent expedition to Ceylon, with a description of the pearl fisheries. Then followed:—Mr. A. O. Walker, on the Amphipoda, Mr. I. C. Thompson, on Indian Ocean Copepoda, Mr. W. E. Hoyle, on the cuttlefishes, and Mr. J. Lomas, on the marine deposits dredged by Prof. Herdman. Prof. Dendy, Mr. Stanley Gardiner and others took part in the discussion that followed. The remaining papers before the Section that day were:—(1) Prof. Cleland, on a hitherto unrecorded element in the occipital bone of seals. (2) Prof. Poulton, on the habits of the predaceous flies of the family Asilidæ, with exhibition of specimens. (3) Prof. E. W. MacBride read a paper on some new points in the development of *Echinus esculentus*. He stated that in order to obtain successful cultures of the larvæ it was necessary to use perfectly ripe parents and to supply the growing larvæ with an abundance of sea water, frequently changed. He pointed out that many cultures on which important conclusions were based were made under insanitary conditions. The cavity of the blastula was at first filled with a thick proteid solution which became thinner as development advanced, and this thinning was possibly connected with the infolding processes in the wall, by means of which the organs of the larva were built up. The larva showed its relationship to Tornaria by the three-fold division of the body cavity on each side and by a larval brain, which was situated at the front end and was independent of the ciliated band. The development of the nerve-ring of the Echinus from the floor of an ectodermic pit was described. A false floor formed over this by the meeting of interradial ridges gave rise to the buccal membrane of the adult. The masticatory apparatus was derived from five pocket-like outgrowths of the left posterior body cavity. Finally, the blood system was a remnant of the proteid contents of the blastocœle added to by exudation from the cells of the alimentary canal. (4) Dr. A. T. Masterman exhibited a series of wax models illustrating the transition from larva to adult in *Cribrella oculata*. The main points brought out were the complete bilaterality of the larva, the sinistral asymmetry followed by axial symmetry converting the larva into adult, and the absence of any true metamorphosis. The changes in the body cavities were shown to agree with the results of Goto for Asterina and Asterias, and to differ from those of MacBride. (5) Dr. J. Hume Patterson gave an important communication, on the causes of salmon disease—a bacteriological investigation, in which he showed that if a sound salmon is placed in water with Saprolegnia there is no result, and that the fungus is effectual only after a preliminary softening of the skin by the action of a bacillus which he had succeeded in isolating and cultivating.

On Monday, September 15, the following papers, &c., were taken:—

(1) Prof. Howes exhibited, on behalf of Mr. J. P. Hill, of Sydney, photographs of the first segmentation stages of the zygote of the native cat (Dasyurus) up to the period of first formation of the endoderm. A 16-celled stage was described, at which the embryo-cells are arranged in a couple of annuli, and later a stage suggestive of over growth of a yolk by the ectoderm. Selenka's blastopore stage was shown to be conspicuous, and in one example the endoderm appeared to arise from a single cell at the point of closure of the blastopore, after the manner of that of Didelphys. Mr. Hill has succeeded in obtaining microscopic

sections of the earlier stages by affixation of the egg to the embryonic membrane of the pig. (2) Prof. J. C. Ewart gave an account, illustrated by the lantern, of some recent inter-crossing experiments with dogs, and pointed out that unless one of the parents was highly prepotent, the first crosses were not as a rule uniform, and that when the members of the cross-bred litters were interbred, some of the offspring very closely resembled the pure-bred grandparents. (3) Mr. Nelson Annandale had a paper on flower-like insects from the Malay Peninsula, and Mr. H. C. Robinson, who had been on the same expedition, gave notes on protective resemblance—both subjects being illustrated by lantern slides. (4) Prof. Poulton then gave lantern exhibitions (1) of British insects in their natural attitudes, and (2) of three-colour slides showing mimicry, protective resemblance, seasonal forms of butterflies, &c. (5) Mr. Thos. Steel exhibited an interesting collection illustrative of Australian zoology, such as the different species of Peripatus, including forms of Ooperipatus which lay fertile eggs having a lengthy period before hatching; also a fine series of land Planarians, also marsupial embryos, the blind marsupial mole, *Notorocytes typhlops*, and the honey ant, *Camponotus inflatus*, both from the Central Australian desert. (6) Prof. R. J. Anderson gave two notes—one on a specimen of the pilot whale of a white colour, with twenty-eight teeth and a large foramen of Winslow in the abdomen; and the second on the relations of the parietal bone in Primates. He showed that the orang is in a variable condition, having sometimes, but not always, a parieto-sphenoidal suture. Other variations were discussed. (7) Mr. A. T. Watson gave a most interesting account, illustrated by the lantern, of the errant habits of the Onuphidæ (Polychæta), and described a defensive mechanism which he had discovered in the tubes. The onuphid worms drag their tubes over the sea-bottom, and protect the open ends by constructing membranous valves, like those of the veins, and so arranged that on retreat of the worm the inrush of sea water causes the valves to close automatically. (8) Mr. R. T. Leiper, on an accœlous Turbellarian inhabiting the common heart urchin. The worm was found in the accessory canal of about 5 per cent. of the *Echinocardium cordatum* at Millport. It is white, leaf-like, and 2·5 mm. in length. There is no spermotheca or vagina. A similar absence of female accessoria obtains in Haplodiscus, from which this Turbellarian differs in the following respects:—(1) shape; (2) parasitic habitat; (3) mouth in anterior fourth; (4) paired lateral testes; (5) no defined vasa deferentia; (6) penis with chitinous knob-like armature; (7) large digestive vacuole. In discussing the classification of the Accela, the author suggests that the family Proporidæ, comprising all Acœla with one genital opening, be subdivided to form two subfamilies:—(1) Proporinæ, to include the genera (*a*) Proporus, (*b*) Monoporus, (*c*) Böhmigia, *i.e.* those with a common genital pore; (2) Avagininæ, consisting of (*a*) Haplodiscus and (*b*) the genus now recorded, *i.e.* those having a male pore only. The name *Avagina incola* is proposed for this new form.

On the Tuesday, Dr. Henry Woodward gave a note on a diagram of the skull of *Mastodon angustidens*. Dr. R. F. Scharff had an interesting paper on the Atlantis problem, in which he collected a number of facts in the distribution of animals bearing upon the possible land connection between Europe and America by way of the Atlantic islands. His investigations tended to show that Madeira and the Azores are the remains of an ancient Tertiary area of land which was joined to Europe, and that it probably became disconnected in Miocene times. As to a land bridge across the Atlantic, many reasons can be given in its favour. Uniting North Africa with Brazil and Guiana in early Tertiary times, it probably subsided during the Miocene period, leaving only a few isolated peaks as islands.

Mr. R. J. Ussher gave an interesting address, illustrated by lantern photographs taken by Mr. R. W. Welch, on the avifauna of Ireland as affected by its geography. He shows that as a result of the position and features of the country, some species breed more numerously and extensively than in England. The buzzard, bittern and capercaillie have been exterminated, and certain other British birds have never established a footing in Ireland. Winter and occasional visitants were discussed, also the list of North American species taken in Ireland. The raven, harriers and eagles are approaching extinction. The bones of the great auk found in kitchen middens in Antrim show that it was used as food.

Mr. E. J. Bles gave two communications, one on the development of Xenopus, and the other on experiments on the Axolotl, showing adaptations to life in an alkaline medium. Dr. H. W. Marett Tims had a paper on the structure of the scales in the cod. Prof. C. S. Minot, of Boston, U.S., gave an address on the significance of the embryonic cell, in which he gave the results of his observations on cellular development in guinea-pigs, mice and rabbits. Mr. J. Stanley Gardiner had a paper on the breaking up of coral rock by organisms in the tropics. First the boring algæ and sponges penetrate the living corals, extending into every septum and spine. They weaken the coral and so riddle it that it is then easy for boring Polychæta such as Polydora and Eunice to enter. Following these come various Sipunculids, the bivalve Lithodomus and the cirripede Lithotrya. Then a wave breaks off the coral mass, leaving a bare surface, which more boring animals at once take advantage of. The fallen coral mass is finally broken down into smaller and smaller fragments by the boring animals. Then the sand-feeders come into action and grind up the coral fragments into sand. Chief among these may be mentioned the sea-slugs, *Holothuria atra* and *Stichopus chloronotus*, which appear to retain within their guts the coarser fragments in the sand for long periods of time, while the finer particles are swept out along the ciliated grooves. Other sand-feeding forms are Sipunculus, Echinus and Ptychodera, the mound-like casts of the latter of which form most conspicuous features of the landscape at low tide. Much of the finer material must pass into suspension in the water and be swept out by the tidal and oceanic currents, while the smaller the sand grains the greater the area they present for solution. It will thus be clear what an important bearing the sand-feeding and boring animals have on the formation of the lagoons of atolls.

Mr. J. Graham Kerr communicated a paper, illustrated by microscopic preparations, on the early development of muscles and motor nerves in Lepidosiren. He described a stage in which the inner wall of the myotome consisted of a layer of large neuromyoepithelial cells, the cell substance of each of which was continued into a tail-like process, which was in turn continuous with the nerve rudiment. The outer wall of the myotome was shown to contribute largely to the formation of the myomere. Mr. Kerr's preparations showed that the connection between spinal cord and myotome existed at a very early period—while the two structures were still in contact—and that these primitive connections—the rudiments of the motor nerve-trunks—became gradually drawn out and lengthened as the myotome receded from the spinal cord with the interposition of mesenchyme. The motor nerve-trunk, at first naked, became later on surrounded by a sheath of mesenchymatous protoplasm.

Mr. G. H. Carpenter, of the Dublin Museum, read a paper on the insect fauna of some Irish caves, dealing especially with Collembola discovered in Michelstown Cave, co. Tipperary, and in Dunmore Cave, near Kilkenny. With the exception of *Heteromurus margaritatus*, Wankel, which has now been found to inhabit caves in Ireland, France and southern Austria, all the blind species enumerated occur in above-ground localities (albeit with a discontinuous range) as well as in various caves in continental Europe. These facts point to the conclusion that such insects may be regarded as the survivors of ancient races with wide distribution whose ancestors were destitute of eyes; now almost exterminated in the upper world by the competition of eyed forms, they still survive in the caves. This conclusion does not, of course, contradict the generally accepted view that a large proportion of the blind cave fauna of continental Europe and North America (probably including *H. margaritatus* mentioned above) must be descended from eyed ancestors.

On Wednesday forenoon there was an interesting discussion on natural selection in relation to protective resemblance and mimicry in animals, arising out of the communications made to the section by Prof. Poulton and by Messrs. N. Annandale and H. C. Robinson. Prof. Poulton, in opening the discussion, expressed his conviction that natural selection was the key to the puzzle, although it was not always possible to say how it should be applied. He gave examples of some mistakes that had been made in the past, and since rectified in attributing utility to characters. He alluded to the results he had obtained from the destruction of chrysalides in different environments, and he finally accepted natural selection as a working theory. Mr. Annandale and Mr. Robinson both brought up various cases observed by them in Siam and Malaya where the

explanation by natural selection seemed very difficult. Mr. G. H. Carpenter pointed out how some of these cases might be explained. Miss M. Newbigin and others also brought up further difficulties, and some speakers discussed natural selection as a form of isolation and as being of less importance than other forms. In his reply, Prof. Poulton dealt with many of the cases cited, and showed how they could be brought under the operation of natural selection.

Finally, a paper by Mr. C. Shearer, on the early development of the head kidney in Polygordius and Eupomatus, and the usual votes of thanks to the president and officers brought a very successful meeting of Section D to a close.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE changed spirit that is coming over geography was in evidence at Belfast. Accounts of explorations proposed or executed were limited in number, and half of them related to the unknown Polar lands. On the other hand, papers dealing with the morphology of limited areas and with applications of geographical knowledge to economic problems, branches of geography which are rapidly growing in importance, this year outnumbered the accounts of pioneer travels.

The president, Sir Thomas Holdich, in his address on the progress of geographical knowledge, emphasised the fact that the area for pioneer work was rapidly diminishing, and that the exploration required was of a more exact and comprehensive character, which necessitated a more restricted scene of operations. He very properly insisted on the need for an exact knowledge of the previous work done in any region before attempting to carry out new investigations in it, and that the investigators should be thoroughly trained men. In much of the world, a topographical knowledge is wanted intermediate between that given by pioneer surveys and that of elaborate national surveys such as our ordnance survey, *i.e.* a knowledge sufficient to show on a fair scale the salient features, and capable of being adjusted to the triangulation of a geodetic survey. Following a recent American authority, Sir Thomas Holdich called this a geographical as opposed to a topographical survey. As geographical survey means a survey of the distribution of all phenomena within a selected area, and not merely of its topographical features, it would be well to find another term. Topography and geography are too often considered synonymous, and it does not help to an appreciation of the true significance of geography to identify it with a topography. Why not simply say large- and small-scale topographical surveys? The president of Section E is the last man to limit geography to topography, as many paragraphs in his address showed, although as a surveyor of long and special experience he naturally dwelt most fully on map making

The travel papers were of a high standard. The audience had to listen, not to uninteresting extracts from diaries, but to well-digested summaries of results. Major Molesworth Sykes discussed the geography of southern Persia, in a paper which might equally well be classed among those applying geographical knowledge to practical needs. He pointed out the influence of the dry, barren conditions of southern Persia and Baluchistan, bounded by an inaccessible coast and so escaping invasion from the sea, in determining a hardy, warlike race, which has held in subjection the plains of Mesopotamia and even of India. He traced the influence of physical features on trade routes and the new telegraph line. Part of his paper was a contribution to physical geography, for it dealt with the changes of the bed of the Helmand River. He remarked that the desert of Lut is traditionally associated with Abraham's nephew, and condemned our maps for distinguishing between it and the Dasht-i-Kavir, as Kavir is the name of Arabic origin applied to all saline portions of Dasht-i-Lut, the general name for the whole desert area. A very serviceable paper was communicated by Captain Ryder on hilly Yünnan, in which the possibility of the much-discussed railway line from Burma was not denied, though its utility or financial success was. The natural route was by the Red River through Tongking, and a railway would soon be ready through the French territory. Mr. Hawes, an energetic young Cambridge graduate, told us how he could find out so little about Sakhalin that he visited it to discover for himself what it was like. It is almost as long as from the Shetland to Land's End, rises to about 5000 feet as Great Britain does, has two rivers each about 300 miles in length, and is covered with the forest primeval, wherein bear, wolf, fox, sable, reindeer and other animals wander. The climate is one of extremes, but popular ideas about a perpetual fog enshrouding it must be abandoned. The natives are the Ainus, Gilaks, Orochons, Yakuts and Tunguses, but the majority of the inhabitants are Russian exiles, few of whom are political prisoners. The Rev. W. S. Green brought us to a little island nearer home and showed views of Rockall. Prof. Libbey, of Princeton University, described his recent visit to Petra and showed magnificent views of its impressive rock temples, tombs and still older "high places" of Moab, and of the gorges through which this depression is reached.

Prof. Libbey read a prophetic note from Sir Clements Markham on the Sverdrup North Polar Expedition, and subsequently gave a graphic account of the expedition to renew Peary's supplies two years ago, in which he took part. Both communications expressed belief in the safety of these explorers, and were verified within a few days. Interest, however, was concentrated on the South rather than on the North Polar regions. Dr. Mill gave one of his admirably lucid expositions, in which he traced the sequence of ideas about a great southern continent and the various phases of Antarctic exploration. A crowded audience listened to Mr. Bruce's account of the plans of the Scottish National Antarctic Expedition, which will concern itself mainly with oceanographical and meteorological investigations, for which it is exceptionally well equipped. Much is hoped from the kite flying by the meteorologists, for which elaborate apparatus has been provided. The audience sympathised greatly with Mr. Bruce, who has unhappily found himself compelled practically to rebuild his ship, the *Scotia*, at the cost of transforming an estimated surplus of 2000*l*. collected above the sum required for the expenses of one year's work into a deficit of 4000*l*. A grant of 50*l*. was voted by the Association to the expedition.

Of physical papers, that which attracted most attention was Prof. J. Milne's account of world-shaking earthquakes, with special reference to the recent volcanic eruptions in the West Indies, of which 93 per cent. are submarine. He associated periods of volcanic activity with periods of upheaval, and those Antillean eruptions of which we possess records with huge readjustments of the Hispaniola-Jamaica fold or of neighbouring folds on the American continent. A report was read by the Committee on Terrestrial Surface Waves and Wave-Like Surfaces, which was drawn up by Dr. Vaughan Cornish, whose well-known recent work was outlined in it.

Prof. Libbey discussed the evolution of the Jordan Valley, the origin of which he traced to a rift at the close of the Cretaceous period. It was subsequently widened and deepened by ice action to the Sea of Galilee, if not throughout its whole length; then submerged nearly as far north as the Sea of Galilee and covered with 4000 feet of sedimentary deposits, which were afterwards gradually elevated, the stream cutting its bed through them the while. Some 3000 feet of this sedimentary rock were removed when conditions altered, and probably the glacier disappeared or the water supply failed, or the rate of elevation increased, or all three took place and connection with the ocean was blocked. After 1000 feet of rise, the present conditions were obtained. Mr. Herbertson read a note on the windings of the Evenlode, and suggested that we must look some 150 feet above the present level, where the river flowed over Oxford Clay, for their initiation. Mr. Porter traced the origin of the valleys of county Cork, which change abruptly from one strath to another, to glacial interference, and explained the meridional character of many tributary glens as the outcome of faulting plus the rapid flow of pre-Glacial streams. Prof. W. W. Watts described the features of Charnwood Forest, where old mountains rise above Triassic deposits which cover their lower slopes, these slopes being here and there exposed in the river valleys. He compared the Triassic landscape in Charnwood Forest with that of the Great Basin of North America at the present day.

A report was read from Dr. T. N. Johnston on the Scottish Lakes Survey, in which the seiches which have been recently observed were described and illustrated by curves. (See NATURE, June 12.)

The only paper on biological geography was that by Mr. Lloyd Praeger on geographical plant groups in the Irish flora. A careful analysis of the distribution of plants in Ireland reveals the existence of several fairly well-defined types. There is a marked tendency to a "central" or "marginal" distribution, the result of the configuration of the country, the central group

being largely composed of lowland, calcicole, and aquatic or paludal species; the marginal of calcifuge, upland and dry-soil plants. Well-marked northern and southern, eastern and western groups also exist, the boundaries between them consisting of lines running not exactly east and west or north and south, but rather north-north-eastward from Cork to Londonderry and east-north-eastward from Galway Bay to Dundalk Bay. For these six types of distribution the author proposes the names Central, Marginal, Ultonian, Mumonian, Lagenian, Connacian, the last four being taken from the old names of the four provinces of Ireland, in each of which one of the groups attains its maximum. The characters of each plant-group, and its relations to the climatological and physiographic features of the country, were pointed out.

Two papers of economic importance were read. Prof. Johnston showed the distribution of peat bogs in Ireland by means of a new map prepared by the Intelligence and Statistical Branch of the Irish Agricultural and Technical Instruction Department. They cover 1861 square miles, chiefly in counties Donegal, Mayo and Galway, and have an average depth of 25 feet. An account was given of the character of the different layers of a bog as seen in a vertical section, and an explanation suggested of the origin of a bog-slide. Specimens of the bog-flora, of the different kinds of peat and of the economic products derivable from turf or peat, lent from the botanical collections of the National Museum in Dublin, were exhibited. The second paper, by Mr. R. B. Buckley, on colonisation and irrigation in Uganda and the British East African Protectorate, began with a clear picture of the existing physical and economic conditions of these dependencies, and enunciated comprehensive and judicious views as to their development in the future. The question of irrigation was exhaustively treated, and the author concluded that the prospects of great transformations taking place through its aid are not very hopeful. A. J. H.

ENGINEERING AT THE BRITISH ASSOCIATION.

ON Thursday, September 11, after the president's address, a paper by Mr. H. A. Humphrey on recent progress in large gas engines was read. This paper, which was illustrated by lantern slides, gave an account of the extraordinary development of large gas engines which has taken place during the past few years, and which has, as the author said, had but few parallels in the history of engineering enterprise. In the Paris Exhibition of 1900, a 600 h.p. Cockerill gas engine was, from its size, the object of much interest. The same makers are now building engines of 2500 h.p., and they are prepared to undertake one to develop 5000 h.p. In this country it is only as recently as 1900 that engines above 400 h.p. have been made, the first two being constructed for Messrs. Brunner, Mond and Co.'s works at Winnington, yet when the paper was written (August) the two chief manufactories in Great Britain had under contract or had already delivered no less than fifty-one gas engines ranging in size between 200 and 1000 h.p. But it is on the Continent and in America that the most remarkable advance has been made. The author gave in a very complete table particulars of all engines of more than 200 h.p. capacity which have been built abroad or are under construction, the total amounting to 327 engines, developing 181,605 h.p. Slides shown by the author illustrated the various uses to which these large gas engines have been put so far, such as dynamo driving, air compression for blast-furnace work, and other similar uses. Perhaps the most interesting detail in connection with this increase in the size of gas engines has been the use of blast-furnace gas for working them. The author in the latter part of his paper explained in some detail the improvements in construction and governing which have made these large engines possible, in particular the changes which have been necessary in the old "hit and miss" governor mechanism, where, as in dynamo driving, perfect uniformity of speed is necessary. As several large engineering firms in this country have now acquired the rights for manufacturing some of the most successful foreign types of these engines, there is little doubt that we are on the eve of important developments in this country in the gas-engine industry, especially in the utilisation of producer and of blast-furnace gases.

In the afternoon of September 11, the Section made a special visit to the harbour works, under the guidance of the engineers to the Belfast Harbour Commissioners, in order that members might see for themselves some of the remarkable developments which have taken place in Belfast Harbour and have been brought about by constant increase in the size of ocean steamships.

On Friday, September 12, the first paper was a brief communication by the Hon. C. A. Parsons on steam turbines, in which figures were given to show the rapid increase in the use of the compound turbine since 1884. Up to 1890, though a number of compound turbines had already been constructed for driving dynamos, the largest size had not exceeded 120 h.p., the total h.p. at that date being 5000; by 1896 the total h.p. had increased to 40,000 and the largest individual plant to 600 h.p., and now the largest unit has increased to 3,000 h.p. and the aggregate h.p. sold in Great Britain to 200,000. On the Continent, also, their use has been rapidly extending, and the total aggregate of horse-power at home and abroad for driving dynamos up to the present time is not far short of 300,000. As a proof of the remarkable economy obtained in the very large machines, the author stated that a steam consumption of 17·3lb. per kilowatt hour had been recorded during a test of a 1000 kilowatt continuous-current machine belonging to the Newcastle and District Electric Light Company; this would be equivalent to about 10·2lb. of steam per i.h.p. hour, a very remarkable figure, and he anticipates still greater economy in the future in turbines of large size when using superheated steam. Many engineers had feared that these machines would fall off notably in their economy after they had been running for some time, but the author stated that careful tests had now been made with several plants to determine the steam consumption after the machinery had been in use for several years, and no appreciable increase had been found. The second half of the paper was devoted to an account of the application of the steam turbine to marine work; seven vessels have so far been fitted with turbine engines, including the two unfortunate destroyers—the *Cobra* and the *Viper*—and the two well-known Clyde passenger boats—the *King Edward* and the *Queen Alexandra*. In addition to these, a third-class cruiser, the *Amethyst*, would shortly be completed, and orders have recently been placed on the Clyde with Messrs. Denny Bros. for the construction of two cross-channel boats which are to have turbine engines of about 8000 h.p.; this means a total of about 83,000 h.p. in use or in construction. Mr. Parsons stated that if the coal consumption of the *Duchess of Hamilton* (fitted with ordinary reciprocating compound engines) was compared with that of the *King Edward*, and if various allowances for the difference in speed of the two boats and for various other factors were made, then the turbine boat showed a saving of 20 per cent.; he again, as at the Dover meeting, prophesied the eventual use of turbine engines for Atlantic liners, cruisers and battleships. In his reply to a brief discussion, in which several points were raised with regard to the use of superheated steam in the turbines, the author stated that he estimated a gain of efficiency due to superheating of about 1 per cent. for every 10° of superheat.

The next matter dealt with by the Section was the report of the Committee on the Resistance of Road Vehicles to Traction, the first eleven sections of which were devoted to a complete *résumé* of the experimental work which has already been carried out on this subject, and to a summary of the opinions which have so far been expressed (based on these experiments) of the effects on traction on the level of the three independent elements of road resistance, namely, axial friction, rolling resistance and grade resistance. The last two sections of the report were devoted to a brief description of the special apparatus which has been designed and made by the Committee; the first series of experiments undertaken will be confined to measurements of the resistance of single wheels. The tractive force will be transmitted through a system of levers to a small ram which presses upon a rubber diaphragm enclosing a space filled with water or other liquid; the pressure exerted by the levers on the ram will vary with the tractive force, and the consequent varying fluid pressure will be registered by a recording pressure gauge of the Bourdon tube type, and since the drum of the instrument carrying the recording paper will be rotated in strict accordance with the movements of the car, a diagram will be drawn giving the tractive force at all points on the journey. The instrument has been so designed that the leverage on the ram can be altered to ensure diagrams of a reasonable size even when the tractive force is very small, and a revolution counter will be used for obtaining independently the revolutions of the experimenta

wheel. Several preliminary experiments have already been carried out, but the main work of the Committee will be undertaken during the forthcoming year. It should be mentioned here that although another grant was given to the Committee by the Association, still its work will be terribly hampered, and in fact will be almost impossible, unless additional funds are forthcoming from other sources; the Committee is doing work of such great importance to the country that it is to be hoped public bodies and all those who are interested in the question of the construction and upkeep of public streets and roads and the best means of road traction will respond liberally to the appeal which the Committee has issued for financial help.

Two other important papers read on this day dealt respectively with the rainfall and water-power available in Ireland. Dr. Mill exhibited a map of Ireland coloured to show the distribution of rainfall, as ascertained from the records of the ten years 1890–1899, and pointed out that practically the whole country west of the Foyle and the Shannon, and west and south of a line drawn from Limerick to Clonmel, had a rainfall exceeding 40 inches in the year. He also gave some interesting statistics as to the number of rainfall stations in Ireland and the increase since the Belfast meeting in 1874; he calculated that 185 additional observers would be required to secure as many rain-gauge observations per 1000 of population as were now made in England. Perhaps as a result of this meeting we may again find an increase of interest taken in this important question.

Mr. Dick, in his paper on the water-power available in Ireland, considered only the cases of the Shannon, the Erne and the Bann, perhaps the most important rivers, however, from a power point of view. The dry-weather minimum flow of these rivers is the vital factor in calculations of available power, and the problem is rendered exceptionally difficult owing to the conditions which have been laid down in reference to this minimum flow in Acts of Parliament which have been passed in connection with the fishing industry in these rivers. Mr. Dick stated that very careful measurements had been made of the amount of water available under the above conditions, and he calculated that as a result the continuous water-power available on the lower Shannon would be nil, on the lower Erne 400 and on the lower Bann 800. He then dealt with the possibility of increasing this small horse-power by storage of flood waters, and came to the conclusion that this was out of the question when regard was paid to the enormous amount of money which had already been spent for the purpose of keeping these rivers at or near their summer level in connection with the requirements of arterial drainage and navigation. It will be seen that the author's figures correct the serious misconceptions that have prevailed in regard to the amount of water-power likely to be available in Ireland; no doubt these too favourable views have arisen from the erroneous figures given by Sir Robert Kane in his book on the "Industrial Resources of Ireland," since that author estimated that the available water-power on the Shannon alone between Killaloe and Limerick was 34,000. Several of those who took part in the discussion were of opinion that the author had taken a too pessimistic view of the situation, and that in several cases, at any rate if useless navigation rights were abandoned, considerable power would be rendered available.

The meeting on Monday, September 15, was, as usual, devoted to electrical papers, and the first paper dealt with was a suggestive one by Mr. J. E. Kingsbury on the future of the telephone in the United Kingdom. The author gave a short history of the various telephone companies which have been at work in this country from the date of the famous action brought against the Edison Telephone Company by the Post Office in 1880, and then went on to show that competing services which had been started in one or two towns, as for example, Dundee, Sheffield and Manchester, had not benefited the community; in fact, the people of those towns had actually derived an advantage from the amalgamation of the local competing companies with the National Telephone Company, a view, we may point out, quite opposed to the popular ideas upon that subject. Mr. Kingsbury was of opinion that competing services had ceased in the past because the absurdity of such a situation was obvious as soon as it was put into practice. Parliament, by the Act of 1899, determined to foster once more, by the help of the ratepayers, this system of competition, although when tried before under private enterprise it had proved unsatisfactory. Both in Glasgow and in Tunbridge Wells, where municipal telephone systems had been started, the author was of opinion that money had been uselessly spent simply to create a system of duplicate subscribers and duplicate subscriptions. In London, on the other hand, an admirable arrangement had been concluded by the Postmaster General by which every subscriber to the Post Office system was in connection with the existing 45,000 subscribers to the old system. In conclusion, he stated that as corporations could borrow money easily and cheaply, it would be spent on competitive systems which were wasteful, and gave the maximum of inconvenience and the minimum of public benefit. Several of those who took part in the discussion were opposed to the position taken up by the author on the question of municipal telephone systems, but Sir William Preece appeared to uphold the idea that a general telephone system could be much better worked by the Post Office than by separate municipalities. One of the speakers declared, as the result of careful inquiry, that the Glasgow telephone system, instead of being a failure as the author had stated, was a great success.

Prof. E. Wilson then read a paper on the electrical conductivity of certain aluminium alloys as affected by exposure to London atmosphere. A number of specimens of various light aluminium alloys had been placed on the roof of King's College, London, in order to investigate the effect of exposure to the atmosphere. The specimens were wires about $\frac{1}{8}$ inch in diameter, carried on a wooden frame, and had been exposed for about thirteen months. A table was presented by the author giving the results of the experiments, and as chemical analyses had been made in every case, the author was able to show the effect upon the specific resistance of each alloy of the different elements in combination with the aluminium; as a result of his work, he concluded that for exposed light aluminium alloys copper alone should not be used; on the other hand, the presence of equal amounts of nickel and copper, about 1 per cent. of each, though it slightly reduced conductivity, produced a marked improvement in power to resist corrosion. Dr. Glazebrook, in the discussion, mentioned how difficult it was in such experiments to determine accurately the specific resistance owing to the pittings and cracks which were produced on the surface by the action of the weather.

Another paper of much interest was one by Mr. W. Taylor on the science of the workshop. He said that the subject would divide itself naturally into three parts—the materials used in the workshop, the processes for their treatment, and tools; and in the section on materials he pointed out truly enough that much of the work which had hitherto been carried on in technical schools and also by original investigators had been confined to the study of the physical properties of materials from the point of view of the designer, whose chief interest is that his machine structures shall not be strained beyond the elastic limit, rather than from the point of view of the mechanic, whose business it is to shape the materials, generally by straining them beyond the elastic limit. He hoped for considerable advance in our knowledge from this latter point of view, from the photomicrographic study of the structure of materials and from such researches as those which have been carried out by the Alloys Research Committee of the Institution of Mechanical Engineers.

The last paper on the programme for the day was one by Mr. J. R. Wigham on a new flashing lighthouse light without intervals of darkness. One of these lights was placed on the top of the tower of Queen's College and was shown in operation each night during the meeting. The author stated that the cost of the new light, which was practically a continuous one, was not greater than that of any other of the first-class lights with revolving annular lenses, and that any common illuminant might be used.

The afternoon of Monday was devoted to a joint discussion with Section L on the training of engineers. The discussion was opened by the president of the Section, Prof. Perry; it was, in fact, a discussion of his presidential address to Section G. One of the points mentioned by the president was the necessity that engineers and manufacturers should interest themselves in the question of the education of the young engineer, and that until they do so engineering teachers cannot hope to meet with success. We feel sure that this want of interest is at the bottom of much of the trouble the directors of engineering schools now experience in inducing parents and guardians to consider that the profession of an engineer is one which requires in the present day as lengthy and complete a preparation as medicine or law. Several speakers

raised the question as to whether it was advisable to adopt what has been called the half-time course, that is to say, the system under which students attend the university or technical college classes during the winter and work in the shops or drawing offices during the summer. We may mention that this plan has been carried out in several towns, but as a rule employers are somewhat opposed to it. Sir William Preece declared—and it is a statement which cannot be too often made—that it is at the top and not at the bottom that we require radical changes in our technical education for engineers.

On Tuesday, September 16, a number of general papers were dealt with. The first paper, by Mr. W. H. Booth, treated of the smokeless combustion of bituminous fuel, and the author contended that as a rule boiler furnaces were badly designed in respect of the prevention of smoke. Furnaces must be arranged in such a way that all the gaseous products of the furnace are swept together with the admitted air, and are not cooled down until sufficiently burnt to admit of their being used for heating purposes; and he was of opinion that there was nothing in smoke prevention to justify the assertion that it was economically impossible. Mr. J. S. Raworth, in connection with this subject, described a system for the prevention of smoke known as the "Wilson smokeless process." A small quantity of nitrate of soda in solution is injected into the furnace with sufficient air to give perfect combustion, the cost being about 3*d*. to 4*d*. per ton of coal burnt; this system has been installed in a tobacco factory in Belfast, smoke has been abolished, and the output and efficiency of the boilers improved.

Prof. G. Forbes then gave an interesting account of his experiences in the late South African war with the infantry range-finder, which he described at the Glasgow meeting last September. Both officers and men who had served at the front were unanimous in their opinion that the great want which had so often nullified the strategy of our leaders and endurance of our men was a quick, handy, trustworthy one-man range-finder. In actual service this range-finder had proved that its accuracy was all that could be desired, and it was much quicker in action than the mekometer. During a trek of 300 miles in eleven days, he had been constantly called upon to give distances, and it never took longer than one minute to dismount from his horse, set up the range-finder and give the first range, other ranges being given in a few seconds. He was in action for two days, and was able to give the ranges quickly and accurately without any unnecessary exposure. With his own eyesight, which was not particularly good, he was able to get an accuracy of 2 per cent. in 3000 yards, but many of the men had been able to get a very much greater degree of accuracy than this.

Several other short communications were read, but we have not space to deal with them. T. H. B.

SCIENCE AND LITERATURE.[1]

ON what subject ought one to speak at the beginning of the session of a College of Science which is also a School of Applied Science, speaking, not only to one's colleagues, but to new and old students who differ from one another in character, training, social position and attainments more than the students of any other college probably in the world? This college has three functions. It gives the highest possible instruction in mathematics and natural philosophy and in all the natural sciences. It gives technical instruction to mining, metallurgical and mechanical engineers. It gives pedagogic training to teachers of all subjects taught at the college. The presence of Sir Arthur Rücker, Principal of London University, reminds me of a fourth function which has recently been added—namely, the preparation of students to pass university examinations.

I am strongly of opinion that every engineer—that is, every man whose business it is to apply any of the physical sciences—ought to have a more or less thorough training as a mechanical and electrical engineer. In the address which I had the honour to deliver three weeks ago as president of the Engineering Section of the British Association, I tried to show that only a very exceptional student can obtain such training unless he spends much time in mechanical or electrical engineering laboratories such as I there described. For many years, from long before I came to Kensington, the mechanics course here has been one in mechanical engineering as well as in mechanical philosophy. My anxiety to own a laboratory has met with the utmost sympathy from the higher authorities and the council of the college. I may say that we are all as anxious that students should work with electric generators and motors and other electric-power plant as with steam and gas engines, with water turbines and pumps. I know that some of you blame me because I can give none of this necessary instruction, and sometimes, perhaps, I blame others for not affording me facilities. The curriculum at this college was arranged a great many years ago, when people aimed only at the training of the exceptionally clever student, and, indeed, before any electrical appliance was used by miners or metallurgists; before the time when a mine became filled with mechanical contrivances. Every mining or metallurgical or other technical school now established in any part of the world gives this sort of training to the students which we are unable to give. The authorities of this College are in sympathy with you and with me, and would help us to this necessary laboratory work and greater space and other facilities for instruction in my division if they possibly could. Parenthetically, I may observe that, in so far as applied mechanics and engineering theory are concerned, the courses of study here will enable any willing student to obtain the highest engineering degree of the University of London.

Some of you are extremely well read in scientific text-books, having passed most severe examinations in pure and applied science. And not mere text-books, but real scientific books have been studied by many of you; for I know that some of you have dipped into Larmor's book on the ether, and have read Thomson and Tait and Maxwell and Rayleigh. Not only have you this wonderful knowledge in science, but you have been earning your own living and you have developed an instinct for taking advantage of chances, of fending for yourselves, of making other people do what you ask, that is perfectly marvellous. Some of you remind me of great fir-trees that I saw in Norway this summer, spreading their roots over a rocky soil, gaining sustenance where no other kind of tree could exist. One power more developed than another is that of passing examinations. Nobody who is without the experience of an examiner of candidates from the evening science classes can comprehend your power of getting marks from a careless examiner for answers to questions on subjects about which your knowledge is limited. There is hardly any town in the British Islands from which our scholars—I suppose that quite a hundred scholars are here—have not come, each picked from many hundreds or thousands, each the recipient of great honour and a valuable scholarship, and your townspeople and your old companions are keeping their eyes on you, wondering whether or not it is a great man of the future that has been sent up to us. And now for the other side. You know much of what has been done, but have you the power to discover, to add to the world's knowledge? Your knowledge has been derived from books and lectures; you have now to learn that a week in the laboratory, during which you seem to crawl, during which for examination purposes you do less than in reading ten lines of a text-book, is really of more value to your scientific education than a month's hard reading. This is almost unbelievable to you who are such adepts in passing examinations; yet it is quite true. Lectures and lessons have spoon-fed you until now; lectures and lessons will in future teach you to feed yourselves.

Again, many of you think it is not only a waste of time, but a positive sin, to read novels and poetry and general literature, to cultivate in any way the imagination, to take an interest in painting or sculpture or music. You have yet to learn that although parrots and other imitative animals can get on without imagination, there is no such thing in existence as an unimaginative scientific man. That you have some imagination and individuality is evidenced by your differentiation from all other students of science classes; but have you these well developed, and have you those other qualities which are absolutely necessary for the success of a scientific worker? Imagination is far and away the most important; but there are also judgment and common sense, and the love of truth and the power of self-sacrifice, which seem always to accompany the pursuit of science. Are you fond of reading? Do you know how to use books? Can you explain with decent sketches what you observe and know? Mere learning is a poor thing, but fondness for reading leads to the greatest possible development of all one's

[1] Abridged from the inaugural address delivered at the Royal College of Science (with which is incorporated the Royal School of Mines), London, by Prof. John Perry, M.E., D.Sc., LL.D., F.R.S., Professor of Mechanics and Mathematics, on October 2.

intellectual and emotional faculties. Fondness for reading will come to you if your companions are fond of reading. English and English subjects are badly taught in schools; hardly anybody anywhere seems able to teach them; one's own reading and discussion with friends are far better for one's education than any course of lectures. However limited your past education may have been, whatever defects some hypercritical learned man may see in the school system under which you have been brought up, starting from your present conditions, if you are fond of reading and have common sense, there is nothing to prevent your becoming men of the finest kind of liberal education. But you must exert your common sense and try to distinguish clearly what is essential from what is unessential in education. English literature is equal to, if not greater than, any literature of any people that exists now or has ever been. The language of our great Empire is enough for any man who is not specially fond of language study. If you love to study foreign or dead languages, do so; but if you are not so inclined you will be acting foolishly to waste your time over them.

The average man cannot be much hurt intellectually by anything he does, but the higher intellect is, I think, easily hurt, and I know of several men who had genius, real genius, whose intellects have been permanently dwarfed by a six months' course of classics pursued with the base object—degrading to classics and to themselves—of becoming able to pass an examination. There are some kinds of moral degradation which are final; the holy of holies has been desecrated once for all. My language about this matter will not probably be understood by more than a few of my hearers, but if there is even one who understands, my message is very important. If such a one is here I would warn him that there are certain prices too large to pay for examination success. I object very much to those examination systems in which certain things are compulsory. Of course, we cannot get rid of all compulsory things. English and English subjects must be compulsory on English students. But I do say that the list of compulsory things should be made as small as possible. I am told that a knowledge of the German language must be made compulsory for chemists and biologists. I am sorry to think that this may be so. But inasmuch as the men who tell me this say that it is the case also for physicists and mathematicians and engineers, I venture to doubt the necessity for compulsion in any case whatsoever. I am perfectly certain that in these days of much publication of translations and abstracts of foreign scientific papers, no kind of physicist or engineer needs French or German or any foreign language so much that it is *imperative* on him to make a study of it The men who insist on the study of a language other than English do not seem to know how difficult such a study is for some students. Time will not allow me to do it here, but I hope some time to have a chance of pricking this compulsory foreign language bubble which everybody is cherishing at the present time without really thinking about its intrinsic value. How often have I heard common men say that they abhor translations; that the style and real flavour of an author are only to be had in the original. I notice that such men read very little. I doubt if the average educated man ever does get that kind of appreciation of a foreign author which the author's educated countrymen get so easily. I have met all sorts of men in my life, and I have never seen reason to alter the opinion of my young days that a lover of reading can get immense satisfaction from a translation—whether it is from Greek or Latin, French or German, Spanish or Italian, Russian, Scandinavian or Hebrew; whether it is Omar Khayyum or the Rig Veda, the Talmud or the Koran, or the Bible. To the lover of English all literature is open. The man who insists on reading "the original" seems to me like a tethered cow, such as we see in Jersey; it crops the grass very closely, but surely it must sometimes sigh for a little more freedom and a more extensive range of grazing! If you had finished your course here I would say to you that we are all getting far too learned in natural science. We read far too many of the latest papers. Some of the greatest scientific workers of our times—men who are constantly advancing the boundaries of knowledge—read almost nothing of what other men do. I wish I had time to give you some interesting, and indeed absurd, examples of this. The average scientific man merely casts his eyes over the twenty or thirty scientific periodicals that every man buys every month; he does not even read that valuable periodical "Science Abstracts," or those abstracts of chemical papers published so voluminously, for he has no time. The men who read everything that is written in scientific journals, not merely in England and America, but also in Germany and France, seem to me to have no time to do anything else; they have no time for scientific work of their own. Indeed, they know so much that a simple investigation such as they might begin upon their own account seems insignificant to them and quite unworthy of the time that they would have to spend upon it. I ask only that in matters like this of foreign languages and so much reading of scientific papers you should really judge for yourselves. In these days you can recognise the manufactured men of science by their taking up a notion without thinking about it, by their inclination to follow a leader as a flock of sheep follows the bell-wether, a phenomenon studied by a famous philosopher named Sydney Ortheris.

When the Prince Consort tried to impress upon this nation those ideas of training in science and art which, if they had been attended to, would have kept us in the front of industrial progress, there was one of his ideas which took root, and which has given rise to the work of the Science and Art Department. I know the faults of the department as well as anybody, but all my life I have been pointing out its enormous services to the country. No other country in the world has anything to compare with it. When I think of our industrial supremacy before 1870, and how during thirty years some of us have been vainly warning a careless people that the combination of wisdom and knowledge which we call science, neglected in the education of all well-to-do people, would lead other nations to the capture of our industries; when I think of the utter failure of our higher educational authorities to recognise facts, I bless the Science and Art Department. For more than forty years, in towns remote from universities, it has been possible for the poorest apprentice or workman to get instruction in natural science. These science and art classes were open to the very poorest. Until lately there were no other classes open to rich, clever students. It is astonishing to me that men should be ignorant of the fact that it is the Science and Art Department which has so far saved our industries. I can speak with knowledge of the engineering industries. Of the many hundreds of thousands of pupils who have successfully passed our examinations, a very large proportion, by the combination of their scientific knowledge or scientific habits of thought with practical workshop knowledge and through their energy, became foremen and managers, and in many cases owners, of works. I need not dwell on the fact that every year since 1869 many Whitworth scholars have been sent out into the industrial world, and I affirm of my own knowledge that these men have become such captains of industry as no other country in the world has at its command.

If only our capitalists had even the most elementary technical training such as is suitable for capitalists, the men educated by the Science and Art Department would alone have enabled them to retain that industrial supremacy the loss of which is being bewailed day by day in the newspapers. Many of our best men are making bricks without straw. They discover, they invent, they project improvements. But if the owner of the works, the son or grandson of the creator of an industry, if all the directors of a company, with however scientific a manager, are quite ignorant of those natural science principles on which the industry is based, if they cannot distinguish between good and evil, there is nothing for the industry except to go upon lines that get more and more old-fashioned until the works stop through inanition. And yet I have heard of cases in which old science students, in spite of heart-breaking failures to interest their superiors, have by dogged persistence maintained works as paying concerns, in spite of competition from American and German and Swiss strategists of the best polytechnic training.

Many of the most successful students hide the source to which they owe their scientific training, because the science class fees are small; the classes are open to the poorest students, and in this country caste feeling so predominates that no man likes to have it thought that he comes of poor parents or that he ever attended a class to which poor students were admitted. If all the successful old Science and Art students comprehended how much harm is being done just now by their careful concealment of the fact that the Science and Art Department used to be, and in many places still is, the only agency through which a scientific training could be given in this

country; if they knew of the development which has been going on for some years in the functions of this department; if they knew the importance to the country of a general recognition of the services of the department, they would, I am sure, refrain from hiding their enormous obligations to it. No Government department has had so much intelligent criticism, because the only people who know about it are its own students, and they have by it been brought up in an atmosphere of scientific criticism.

And here are you students—about half of you—the picked men of these science classes, caught in our net, the net that Huxley spoke of, selected from thousands of students who are themselves select, selected that we may train most of you to be leaders of scientific thought or great appliers of science, or great teachers of science! There is the idea that for the good of the country our net has caught in one of you the young man most likely to repay cultivation, and I cannot too often repeat that it is not for your sake that this is done. If one of you happens to be a potential Faraday, however poor he may be, and so far as I can see he is just as likely to be poor as to be rich, it is our duty to try to discover him and give him chances of development. We are supposed to give you enough money to live upon; we ask no fees from you; we set you as men whom the King delighteth to honour, side by side with the most promising fee-paying students—men from our public schools, men taught to admire what you have done in the past, encouraged to think you men of promise—and we ask you to develop those exceptional faculties which to you are your own, but which we believe to be national assets.

I will conclude this address by bringing another and much more important problem before your consideration. The matriculation examination of a teaching university has this meaning only—that it is inadvisable to admit men who are obviously unfit to benefit by the instruction given in the university. When in mediæval Europe all university lectures were given in the one universal language, Latin; when men from all nations came to hear the same lectures, it was evident that no man ought to be admitted who had not enough Latin to be able to comprehend the lectures. As present in Glasgow it is assumed that everybody has had the usual school training, and the only matriculation is in signing one's name in a book. Hitherto at this college men who have passed certain examinations in elementary natural science are thought to be fit and proper students, and of course you scholars who have all passed rather difficult examinations in natural science are admitted without question. I am glad to think that every student admitted to this college does always seem capable of benefiting by our instruction; but if you consider what our object is, the education of true scientific men, you will see that there is something much higher than is attempted elsewhere.

Merely to be able to benefit by the instruction, that is a small thing. Men who come here with valuable scholarships are expected, not merely to benefit, but to benefit in a very exceptional way. They are supposed to develop to the very utmost their obvious scientific ability. To test for this likelihood of development in even the roughest way is evidently difficult. Even to apply any test outside the old limits seems difficult, because of the peculiar circumstances under which you are selected for scholarships. In more than half your cases you are not aware beforehand that you have a chance of being selected. You joined science classes merely to obtain a kind of knowledge which would be useful in your daily work. Your prospects were those of a workshop with a slow rise to foremanship. Your spare time was meagre; it was stolen at enormous sacrifice from family duty and from those pursuits which make a man popular with his fellow workers; the study of language and literature was comparatively unimportant to you, and you were suddenly told that your scientific talents were such that you were selected for the higher life, the life of the seeker after truth; of the man of brains rather than muscle. In seven cases out of ten, it was quite impossible for you to prepare yourselves for any examination in language or literature in the two months before entering this college. I wish I saw clearly what ought to be done. You are valuable material, and if you come here without that training in your own language, that love of reading which leads to the power to use books and the knowledge of all subjects derivable from books, I am quite sure that you are greatly wasted. I have a solution of this problem, but I am not sure that it is the best solution, and therefore I leave the problem for you yourselves to consider.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PARLIAMENT reassembled on Thursday, October 16, for the resumed debate on the Committee stage of the Education Bill. In moving a resolution to give Government business precedence of all other matters during the remainder of the session, the Prime Minister took the opportunity to point out that the main object of the autumn sitting was to pass the Education Bill. The Committee has since its reassembly been engaged upon Clause 8 of the Bill, which defines the powers and duties of local education authorities and the managers of schools. The part of the clause passed reads as follows:—"The local education authority shall maintain and keep efficient all public elementary schools within their area which are necessary, and have the control of all expenditure required for that purpose other than expenditure for which, under this Act, provision is to be made by the managers." As we go to press the subsections of this clause are under consideration.

AN appendix to the calendar for the session 1902–3 of the University College of North Wales provides a very complete account of the agricultural department, which has been much developed since its inauguration in 1888. In addition to the ordinary entrance scholarships and exhibitions open to all students entering the College, there are five scholarships for which students proposing to take the agricultural course may alone compete. The College offers a diploma in agriculture, and students may enter for the degree of bachelor of science, in the group of agriculture and rural economy, in connection with the University of Wales. In cooperation with five county councils, a complete scheme of "out-college" work in agriculture has been organised.

THE many good results which will eventually follow the reconstitution of the University of London are heralded by the new departures in the work of University College, London, all of them explained fully in the calendar for the session 1902–3. Complete university courses of study in the various faculties included in the work of the College have now been established. Among other developments are the institution of a full sessional, instead of a terminal, course in the psychological laboratory; the endowment of the department of pure mathematics by Mr. Astor; the reorganisation of the department of chemistry and the appointment of Prof. Collie to the chair of organic chemistry; the institution of a new matriculation examination for engineering students and the reorganisation of the curriculum preparatory for the diploma in engineering.

THE University of Birmingham *Engineering Magazine* (a well-edited little paper published by the University Engineering Society) contains in its October number an article on continental methods of training engineers, from the pen of Dr. D. K. Morris. The author considers that the chief differences in the courses of study are due to the high quality of the preliminary training and to the number of students. The latter enables special courses to be held; a student can in consequence take, in a subject not actually his own, a course which is specially suited to him, and has not to rest content with taking part of the general course for students of that subject. The electrical laboratories, it is said, have outdistanced those for civil and mechanical engineering, and a special feature in some of the technical high schools is a loan collection of the latest types of machinery provided by the leading manufacturers. Certainly a striking feature of technical education abroad seems to be the cooperation of the manufacturers and the teachers.

THE calendar of the Bristol University College for the session 1902–3 reveals the existence of very satisfactory cooperation between the college and the manufacturers and other employers of labour in the district. In addition to a college engineering scholarship competed for annually, many of the local engineering firms have recently consented to give entrance scholarships to their works. The students nominated will obtain the combined college and works' education for about 50*l.* a year, whereas the ordinary premium paid by non-collegiate students in works is in general 100*l.* annually. The college council has consented to allow any firm offering these concessions to send one deserving apprentice to the college to attend the day lectures at half fees. A large number of local civil engineers, manufacturing engineers and architects have expressed approval of the courses of instruction arranged for students entering upon any of the careers they respectively represent.

In his introductory article to the recent volumes of special reports dealing with American education and issued by the Board of Education, Sir Joshua Fitch very wisely insists that "the progress of mankind is to be secured, not by uniformity or by exact imitation even of the best models, but by differentiation, and by the evolution from time to time of new varieties of type both in principle and practice. Each nation must work out its own problems, in view of its special circumstances, its environment, its past history and its own national aspirations." It is well that English administrators of education should acquaint themselves with the work of the schools and colleges throughout the world, but there must be no attempt to transplant bodily any foreign system of instruction, for the national circumstances and genius are here different from those of other countries. Attention is directed to the fact that American educational reformers look with most confidence for help and guidance to "eminent teachers and professors rather than politicians or official personages." This, at least, is a practice which could be followed with advantage in this country.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, October 7.—Mr. Charles Bailey, president, in the chair.—A paper was read by Mr. R. L. Taylor on the reaction of iodine with mercuric oxide in presence of water. In a former paper he had shown that, when aqueous iodine is shaken up with precipitated mercuric oxide and rapidly filtered, the filtrate contained 80 to 90 per cent. of the possible amount of hypoiodous acid. Messrs. Orton and Blackman have stated, in a paper read before the Chemical Society, that the solutions obtained from iodine and mercuric oxide contain only a small quantity of hypoiodite, the iodine existing mainly as iodic acid. Mr. Taylor concludes from the description of these experiments that the authors overlooked the extremely unstable nature of hypoiodous acid. They used ordinary powdered iodine, which is not sufficiently finely divided, and they took a great deal too long over their experiments. Using precipitated iodine and performing the experiments as rapidly as possible, Mr. Taylor finds that with from ten to twenty-five times as much iodine in proportion to the water as he formerly used, the solution contains from 44 to 52 per cent. of the possible amount of hypoiodous acid and very little iodic acid.

PARIS.

Academy of Sciences, October 13.—M. Bouquet de la Grye in the chair.—On the laboratory registers of Lavoisier, by M. Berthelot. A *résumé* is given of the second volume of laboratory notes of Lavoisier; the contents are not so valuable as those of the first and third volumes. The most important experiments described are those dealing with the calcination of lead and tin in closed vessels.—On some peculiarities of the theory of shooting stars, by M. O. Callandreau.—A general demonstration of the construction of light rays by curved wave surfaces, by M. J. Boussinesq.—Study of iodine pentafluoride, by M. Henri Moissan (see p. 637).—On the hematozoa in marine fishes, by MM. A. Laveran and F. Mesnil.—Carbonic acid as an agent of choice in experimental parthenogenesis, by M. Yves Delage.—The fourteen large laboratory registers of Lavoisier. The register stated to be lost and which has been recently found, by M. H. Brocard. An account of the discovery in the library of Perpignan of the volume of laboratory notes referred to by M. Berthelot above.—On the reduction of the linear element of a surface to a specified form, by M. M. Servant.—The magnetic and electric deviation of the Becquerel rays, and on the electromagnetic mass of the electrons, by M. W. Kaufmann. The results of the experiments quoted are completely in accord with the theory of M. Max Abraham, and it may be regarded as proved that the mass of the electron is entirely electromagnetic, that is to say, the electron is nothing but an electric charge distributed over a volume or surface of minute dimensions, not exceeding 1 cm. $\times 10^{-13}$.—On a consequence of the kinetic theory of diffusion, by M. J. Thovert. The motion of a diffusing material being considered as proportional to the mean velocity of the molecule, the application of the kinetic theory to substances dissolved in a given solvent leads to the prediction that, at constant temperature, the product MD^2 should be constant, M being the molecular weight and D the constant of diffusion. By a method described in a previous paper, the diffusion constants of about twenty non-electrolytes have been determined in aqueous solution, and it has been found that the theoretical conclusions are fairly well borne out by experiment, the constant MD^2 varying between 55 and 67. The author suggests the practical application of the method for the determination of molecular weights.—The methyl ester of methylanthranilic acid in the vegetable organism, by M. Eugene Charabot. The essential oil from the leaf of *Citrus madurensis*, obtained by distillation with steam, contains about 50 per cent. of methyl methylanthranilate.—On cedar wood essence from *Cedrus Atlantica*, by M. Émilien Grimal. A sesquiterpene, cadinene and a ketone have been isolated from the oil.—On a new reaction of formol, serving for its detection in foods, by MM. Manget and Marion. Use is made of the colour reaction with amido-phenol.—Stimulants and nerve poisons, by M. N. E. Wedensky.—On the nerve centres in the Acephalæ, by M. Louis Boutan.—Excretion in the higher Crustacea, by M. L. Bruntz.—On the composition of some reserve hydrocarbons in the albumen of some palms, by M. E. Liénard. The albumen of the palm contains a small quantity of a reducing sugar, a little cane sugar, several condensed mannanes and a galactane.—On the geological constitution of the neighbourhood of Alexandria, Egypt, by MM. R. Fourtau and D. E. Pachundaki. The rocky bar which forms the Alexandrine coast, and which protects the Nile delta against the sea at high water, belongs to the Quaternary epoch, and rests upon the limestones of the Upper Pliocene.—On the general causes of seismic instability in India, by M. F. de Montessus de Ballore.—On a new method designed to facilitate writing and calculation in the blind, by M. Dussaud.

MODERN SCIENTIFIC GEOGRAPHY.

The Nearer East. By D. G. Hogarth, M.A. (The Regions of the World. Edited by H. J. Mackinder, M.A.) Pp. xvi+296. (London: Heinemann, 1902.)

IT has long been a reproach to the British nation that it, the greatest, if not the only real, colonising nation of the West, undoubtedly also the most travelled nation of the world, devotes less time and trouble to the study of geography than any other people. The manner in which geography is taught, or rather is not taught, in our great public schools is indeed more than a reproach to England, it is a disgrace. Great geographers we have had and have; our disgrace lies in the fact that geographical instruction is well-nigh omitted from the curriculum of the schools which our upper classes are accustomed to patronise, our reproach in the fact that the average English "classical" schoolmaster would probably prove ill-fitted to impart such instruction were he given the opportunity and the means of doing so. What average "educated" Briton could answer a series of simple questions on the geography, commerce and politics of the Persian Gulf? Yet a German observer would probably consider it remarkable that the citizen who may have ere long to cast his vote this way or that as to whether Russia is to be peacefully allowed to extend her sway by Teheran to Bushire and Bandar Abbas, or is to be forcibly prevented from doing so by war, should know practically nothing of a matter which may have an outcome most vitally affecting his empire and himself!

Of late, however, we seem to be trying to improve ourselves a little in this matter of general geographical knowledge. The University of Oxford has created a Readership in Geography, and it could have found no better man to fill the post of Reader than Mr. Mackinder, whose energetic geographical propaganda is deserving of the highest praise. The series of handy and useful books entitled "The Regions of the World," of which he is editor, does indeed "supply a long-felt want," for it is calculated to supply, not only valuable books of reference to the merchant and the politician, and interesting manuals for *Selbstunterricht* to the don and the schoolmaster, but also readable and informing volumes which will reach the average patron of Mudie's Select Library, which is exactly what one wants.

The preparation of the volume which deals with the "Nearer East" has been confided by Mr. Mackinder to hands in all respects fitted to deal with it. Few know the lands of the Levant better than Mr. Hogarth, and though he may not have seen the Arabian waste or the wall of Elburz with his own eyes, yet no reader of his book can doubt his capacity to use the eyes of others to the best advantage, and it can certainly be said that the portions of his work which deal with Arabia and with Persia suffer in no way from the fact that he himself has not yet visited those countries. They emphatically give the lie to the pretension that no man may write a book about a country unless he has been there himself.

As to the limits of the "Nearer East" opinions may differ. Mr. Hogarth rules out the whole north coast of Africa west of Egypt; yet Cyrenaica and Tripoli are of the Nearer East, and, though we may consent to omit Algeria because Algiers is a French city, surely Morocco is of the East Eastern. But Mr. Hogarth sets his frontier in the Libyan Desert, and, all things considered, we have no fault to find with him for having done so.

The boundary-line of his territory runs eastward from the northernmost limits of Albania across the "Balkan Peninsula" to the Black Sea coast of Eastern Rumelia; thence to the Caucasus and the Caspian, and then south-eastward across the desert which divides Khorasan from Kerman and Irak to the limit of Baluchistan on the Indian Ocean; thence round Arabia and up the Red Sea to a point on a line with Aswân; then along the historical southern boundary of Egypt proper to the Western Desert, and so northwards west of the Oases up to and across the Mediterranean and up the Adriatic to his starting point.

The author deals with the various lands comprised within this boundary in this order: first, "The Balkan Belts," then "The Asian Ascent," then "The Central Upland," then "The South-western Plains," lastly "Egypt." In the "First Part" of the volume these lands are thus generally described; then follow three chapters on their geological structure, their climates and their "Physical Circumstance." In the "Second Part" the human inhabitants of the Nearer East first appear upon the scene, in chapters dealing with their distribution and grouping, the products of their lands, their communications, and their life under the varying conditions which obtain in the various regions described. A chapter on "World Relation" finishes the book. Maps are frequent and, on the whole, good.

This is a modern scientific geography book, systematic in plan, clear and picturesque in description, and, above all, "giving to think."

Upon the excellence of the general plan of the work we need enlarge no further. So far as description is concerned, what could be better than the following impression of the great island which fences in the Hellenic world to the south with its mighty mountain barrier:—

"A serrated and shaggy wall, rising from a wind-tormented, inhospitable sea, and interrupted by three main depressions, of which two are low; little locked pans and long verdant valleys, hidden inland behind spurs; spontaneous vegetation wherever the north wind is shut away—such is the impression left by Crete" (p. 123)?

Or take this, of the Egyptian desert (p. 142):—

"The Egyptian wastes are of limestone formation from the sea to Silsileh. . . . Accordingly, except between Silsileh and Aswan, the traveller will expect to find in the desert all varieties of contour, hill and cliff, valley and gorge, beds of streams and of tributary rivulets; yet neither verdure nor water, but a skeleton of earth, such a landscape as may be imagined in the moon. . . . And here and there in the hollows and wadis will be even such tussocky vegetation as camels love, drawing its life from a hidden humidity . . ."

Space forbids our giving the whole of the description which follows of the prospect which greets the desert traveller on his arrival on the brink of the Nile valley; we must therefore content ourselves with the following:—

"Small clumps of palms mark the villages, and now and again, but rarely, lengthen or widen out into larger plantations. What other trees there are, sycamores, tamarisks, or thorns, stand for the most part singly near the desert edge. The squat mud cabins, dominated often by the white 'Italianate' house of a *sheikh*, are raised a little on their own débris. The long line of a curving dyke, carrying beside a canal a cultivation road or a railway, cuts the horizon. The angles of white sails or a smoky funnel indicate the river; the chimney of a sugar factory is a landmark for miles. The rest is one flat stretch of varying hues, brown, green, red or yellow, according to the season, or is for two months a burnished sheet of inundation, now wider, now narrower, now defined by high cliffs, now melting into an easy gradient of desert, now more to east, anon more to west of the central stream. . . . Serious change in the landscape occurs only far south and far north. Above Silsileh the green belt narrows to a thread. Golden ruin of the sandstone slides on the west almost to the margin of Nile, and low cliffs rise steeply to east with little interval of plain; and presently, with the intrusion of plutonic rocks, the scenery loses all amenity and the river flows with obstructed current between beetling crags which only recede to admit the naked waste within a few yards of the stream. Far northward again the deep lands grow ever more salt and sodden, till reedy marsh supervenes and passes insensibly into permanent inundation; and shallow and slimy meres with few intervals stretch all the length of the Delta base, washing their wavelets on the low sand hills and bars of stony beach, which scarcely keep out the discoloured sea."

Mr. Hogarth does not say much of the peculiar beauties of Egypt, beauties of distance and of light: the Arabian wall above Gîrga seen from the Libyan cultivation-border, nine or ten miles away, through and over a noonday haze; the bastions of Kaṣr es-Sayad or the three peaks of Gebel el-Geir at sunset, salients aglow with richest rose, recesses blue with deepest indigo; Luxor approached across the western sands towards evening, when even that abominable castellated villa-residence which flies the Dutch flag cannot spoil the marvellous effect; things not only not to be forgotten, but to be seen again, for no country excites in the minds of most such a *Sehnsucht* as Egypt. Greece does not; were it not for her historical associations she would be of no more interest to the average man than is Albania; she possesses naturally no such fascination as Egypt, beautiful as she is.

"The natural beauties of Greece," says Mr. Hogarth (p. 122), "are those of distance, beauties of outline on a large scale, beauties of white snows and grey rocks in juxtaposition to an ever present sea of deepest blue, beauties of opalescent lights cast by oblique rays shining through suspended dust raised by the daily winds."

Beauties of detail there are few; all is so patchy and scrubby. Yet what can be more delightful than the view as one descends to Marathon from above Araphên, looking over the broad Gulf of Petali to where Ocha raises its mighty snow-clad mass into the sky? Of the views of Greece from Lykabettos or from the splendid Frankish castle which crowns the Lárissa of Argos we need not speak; the first at least, or its smaller edition from the terrace of Niké Apteros, is almost too well known, especially at sunset; but the second enables one to realise very well the small geographical extent of continental Hellas, for from the keep of the Lárissa the eye can range from Parnon to Parnassus, roughly then from Sparta to Delphi.

Greece plays impudence to Egypt's dignity. Monotonous this dignity may be, yet this very monotony only serves to make it the more impressive. Such beauty as Greece has Egypt does not possess, beauty of sea and snow-mountain; yet nothing in Greece can so subdue the beholder to its fascination as can those interminable bastioned hills with the sand-billows washing half-way up their sides, those curving, branching wadis behind them where on the sand the once water-worn boulders lie blackened by ages of exposure to an unpitying sun, or that monotonous fen which with its palm-clumps, its strings of laden donkeys or camels winding their dusty way along the raised *gisrs* or causeways, its innumerable *sakiyas* each with its boy (in charge of the motive power, a pair of oxen or buffaloes), chanting his monotonous song in duet with the groaning of his machine as he is carried round and round, stretches away to where in the hazy distance a shimmering line of cliff marks the opposite limit of Egypt. Greece always interests and often charms; Egypt *imponirt*.

We have said that Mr. Hogarth's book gives the reader much to think about. Naturally this is very much the case when he touches on political matters. His touch is light, as befits a book of this kind; his intention is simply to draw the reader's attention to matters with regard to which it is necessary that he should form some opinion for himself. The Persian Gulf, for one example, the future of Arabia for another. Is the Power which holds Aden and Cairo and dominates Muscat and Kowêt eventually to hold sway at Er-Riadh and Hayil either as she now rules at Ajmír or as she controls Bikanír or Baluchistan? This is a question which will have to be faced in the future.

Mr. Hogarth's appreciations of the peoples who inhabit the region which he describes are interesting; his note on the modern Greek character (p. 241) is worth quoting:—

"Unprejudiced appreciations of the character of South Balkan peoples are very rare. The Greek character, especially, is seldom treated justly by a northern observer, apt to remember the ancient Hellene too much or too little. The Oriental element does not give endurance and dignity to Latin decadence in Greece as in Spain, because it is not due to the intrusion of a strong Oriental race. To be fair, the Briton must overcome his strong aversion to ideas without works. . . . In published accounts of the Greeks one has usually to do with social, religious, or scholarly idealists with little knowledge of the realities. To their views a course of Byron's letters from Greece and Finlay's final volume supplies a salutary corrective."

Strictly speaking, we might cavil at Mr. Hogarth's attribution of modern Greek want of stedfastness and want of dignity to the intrusion of an Oriental race not so strong as that which has intruded into Spain. Dignity Spain has, but grit she has no more than Greece; surely also the Turk is, as an Oriental, really stronger than, if not so dignified as, the Arab.

An editorial note at the beginning of the book tells us that

"Owing to Mr. Hogarth's absence in Crete at the time when it was necessary that this book should go to press,

a few errors have unfortunately remained uncorrected. These he has noted on p. xvi."

One or two have still escaped the author's notice. Muscat is ordinarily spelt by him "Maskat," but once "Mascat" appears; and no regular rule is followed with regard to the hyphening of Arabic compound names; thus we have "Roba-el-Khali" (p. 73), but "Wadi er Rumma" (p. 71), which is spelt "Wadi-er-Rumma" in the index. So in other cases. The correct form, of course, is Roba el-Khali, Wadi er-Rumma; only one hyphen is necessary.

We are at one with Mr. Hogarth as to the undesirableness of too pedantically accurate a transcription of Oriental names, but it seems to us that "Hadramut" and "Riad" would be better replaced by Hadhramut and Riadh, which we can pronounce even if the Germans cannot. And though Mr. Hogarth defies the pedant with his "Bedawins," we are unable to back him up in his defiance; "Bedouins" or "Beduins" may be all very well, but not "Bedawins"; either "Beduins" or "Bedawîn," one or the other.

In the maps there are one or two mistakes which need correction; for instance, in Fig. 36, "Yidda." In Fig. 16 the railway is made to cross the Nile immediately south of Siut, which is itself placed much too far south. In reality the railway crosses further south than in the map, at the Nag' Hamâdi bend. South of Aswân, spelt here and in other maps "Assuan," the railway gets wrong again. There is no line between Shellal and Wadi Halfa, and there *is* a line along the Nile bank south of Wadi Halfa, which runs as far as the Third Cataract, to Kerma. In Fig. 49 the Athens-Kephisia-Lavrion line is not inserted at all, nor is the new Athenian "underground" from the Theseion *viâ* Monasteráki to the Omonoias. It is true that these are only sketch-maps, but if the railways are inserted in them at all, they should be inserted correctly. In the fine ethnographical map opposite p. 176, we do not quite like the unhesitating colouring of Egypt with the Semitic yellow; there should be some brown or other coloured stripes across it. Nor do we think that pure brown should begin with the Wadi Hammâmât; Nuba is not spoken north of Darâw, south of the 25th parallel, so the line should run north-eastward from Darâw to Kuṣêr. Should there not also be some Magyar, Szekler and Teutonic stripes and spots in the portion of Hungary and Siebenbürgen which comes into the upper left-hand corner of this map and is entirely coloured with Rumanian purple? It is true that the book does not deal with these parts at all, but if they are coloured in the map, the coloration should be correct.

For these cartographical slips Mr. Hogarth, of course, cannot be held entirely responsible. We point them out merely that they may be corrected in the second edition. They in no way detract from the value of the maps as a whole.

One thing we regret, the absence of photographs. A few pictures of salient features of the land—a Greek isle, a desert wadi, a Cilician gorge—would have added greatly to the interest of the book.

We welcome Mr. Hogarth's work, then, not only as a notable contribution to geographical literature, but as a book which will—as is the idea of the series—appeal to a larger public than the members of scientific societies, and will probably not only cause its general readers to take an unwonted interest in geography, but will also direct their attention to threatening political questions for which sooner or later they will be called upon to help to devise a solution.

H. H.

CHEMISTRY AND LIFE.

Das Eisen als das thätige Prinzip der Enzyme und der lebendigen Substanz. Von N. Sacharoff. Pp. 83. (Jena: G. Fischer, 1902.) Price M. 2.50.

THIS philosophical treatise, originally written in Russian, is presented to us in a translation by Dr. Rechtsamer. Without going so far as to say it is of the first importance, it may be safely affirmed that it will be welcomed by physiologists as a contribution to the discussion of the more obscure chemical processes connected with the life of the protoplasm. The author at the outset reviews the different hypotheses that have been advanced as to the intimate constitution of living matter, and finds them all unsatisfactory. He holds that the behaviour of protoplasm cannot be attributed to either its organisation, or its chemical composition or structure, and suggests that all the vital processes must be regarded as arising from a decomposition or splitting of the living substance in consequence of the access of oxygen, followed by a series of recombinations. Hence he turns to a study of the nature of this auto-decomposition with a view to determining its cause.

Proceeding to the action of oxygen in the animal and vegetable cell, and seeking for something universally present therein which is capable of easy oxidation, and of yielding compounds which can be reduced again or further decomposed with comparative ease, he considers he has found it in minute traces of iron. He puts forward accordingly a hypothesis of his own, to the effect that the various vital phenomena of protoplasm are set up by the oxidation of a minute trace of iron contained in the living substance, with subsequent or concurrent hydrolysis.

This theory is examined at some considerable length in the subsequent chapters, attention being given first to enzyme action, which he takes as one of the most remarkable of the metabolic processes. His views on this point will not commend themselves to all physiologists, but he argues in favour of them with some skill. After reviewing the theories of enzyme action advanced by Liebig, Nägeli, Berzelius, Würtz and more recent writers, and quoting published experimental evidence of the action of several of these bodies, he suggests that the active principle of enzymes is a substance which is capable of auto-oxidation and auto-reduction, and that the working which they exhibit depends upon alternate oxidation and reduction of this active principle. An experiment of his own with papaïn may be quoted in illustration of his view. He prepared a solution containing 2 per cent. of papaïn and heated it to boiling. Taking another solution of the same enzyme, containing 10 per cent., he prepared three tubes. No. 1 contained two drops of this active extract and 10 c.c. of the boiled extract; No. 2 two drops of the active extract with 10 c.c. of water; No. 3 10 c.c. of the boiled extract alone. He added to each a

measured amount of gelatin, on which papaïn works. No. 1 digested the gelatin much more rapidly than No. 2, while No. 3 was inactive. As both Nos. 1 and 2 contained the same amount of active enzyme, he considers it certain that the boiled solution contained some constituent necessary for the action of the papaïn. The solvent action of papaïn on gelatin thus requires the presence of two substances, the enzyme itself, which is split up and destroyed by heating, and another substance which is contained in the heated enzyme.

He considers subsequently at some length the group of oxidases, possessing in such a great degree the power of taking up oxygen and communicating it to the bodies which they attack.

The conclusion is that there exists in all enzymes the substance already alluded to, and that this is an iron-containing nuclein. He gives the name *bionuclein* to this hypothetical body.

It would be too long a task to follow the author through all the developments of his theory. They may be gathered from the statement he makes in his third chapter, that since the chemistry of all vital phenomena must be fundamentally the same, the processes which are the foundation of enzyme action must be also the foundation of all vital phenomena, and all must alike depend upon the oxidation of bionuclein. In his later chapters he deals with the behaviour of the cell substance, the fusion of sexual cells, the phenomena of karyokinesis, the phenomena presented by muscle and nerve and by the central nervous system.

The treatise is one which is deserving of careful consideration, though it is doubtful how far many of the author's conclusions will be held deserving of support.

TWO ASPECTS OF THE THEORY OF PROBABILITY.

Probabilités et Moyennes géométriques. By Emmanuel Czuber. Translated into French by Herman Schuermans, with a preface by Charles Lagrange. Pp. xii + 244. (Paris: A. Hermann, 1902.) Price Fr. 8.50.

Philosophical Essay on Probabilities. By Pierre Simon Marquis de Laplace. Translated from the sixth French Edition by Frederick Wilson Truscott, Ph.D., and Frederick Lincoln Emory, M.E. Pp. iv + 196. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.)

WE have here two books dealing with widely different aspects and applications of the theory of probability.

Prof. Czuber's treatise is a collection of problems relating to probabilities in which the number of cases of success and failure, instead of being finite or at any rate discrete, is continuously infinite. The cases considered relate to points chosen arbitrarily on a line, in a plane or in space, to lines drawn arbitrarily in a plane or in space, to surfaces taken arbitrarily in space, and to mean values depending on such random constructions. Such problems have a great interest for the pure mathematician, and they lead to a number of apparent paradoxes depending chiefly on what is meant by "taken at random," and many of these have been the subject of much controversy. No better preparation for the study of such paradoxes can be suggested than a comparison of the results of choosing a point so that all values of its Cartesian coordinates are equally probable with the corresponding results when all values of the polar coordinates are equally probable. The author has made an extended study of the problems proposed by various English writers in the *Educational Times*, of the writings of French mathematicians, and in particular of the important memoir of 1868 by Crofton. The result of this study has been the insertion of a number of historic notes and remarks, including a brief but full discussion of the famous "needle problem" of Buffon, *i.e.* the problem of calculating the probability that a needle dropped at random on a sheet of ruled paper should cross one of the ruled lines when the needle is too short ever to cross two lines. The author quotes Dr. Wolf's experimental tests, which gave a result falling well within the limits of probable error.

The second book is a translation of the famous philosophical essay by Laplace, which was originally based on a course of lectures given by him in 1795 at the École Normale when he was appointed professor of mathematics with Lagrange as a colleague. It is purely philosophical, and deals with general questions arising out of probabilities and hope, their applications to natural philosophy, to prediction of the decisions of juries and other assemblies, to problems of life insurance and to the dispersion of superstitions. In regard to the latter use, Laplace's words may well be quoted:—

"All these prejudices and the terrors which they inspire are connected with physiological causes which continue sometimes to operate strongly after reason has disabused us of them. But the repetition of acts contrary to these prejudices can always destroy them."

There are few illusions arising from a failure to appreciate the calculus of probabilities which have done so much harm in the world as that which has given rise to the confirmed gambler or speculator. The very definite mental impression produced by a valuable prize and the difficulty to form a tangible conception of the probability factor which reduces the expectation to one of loss have proved fruitful sources of revenue to organisers of lotteries. But there is another cause which prevents a study of the theory of probability from saving the gambler from ruin. If in a game of even chances red turns up twenty times in succession, it is still an even chance whether red or black turns up on the twenty-first time; but no amount of mathematical reasoning will enable the confirmed gambler to realise that a previous run of bad luck gives no grounds for the expectation of recovering his losses by a run of good luck in the future.

OUR BOOK SHELF.

Upland Game-Birds. By E. Sandys and T. S. Van Dyke. Pp. ix + 429; illustrated. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 8*s.* 6*d.* net.

THIS is the first of a series of ten volumes on American game and fish, published under the title of the "American Sportsman's Library," which has come under our notice; and if its companions are anything near so good as the

one before us, the series ought to command a large sale among both sportsmen and naturalists. Indeed, the mere fact that all the volumes are to be issued under the editorial supervision of Mr. Whitney, the well-known editor of *Outing*, ought of itself to be a sufficient guarantee that they will be all such works should be. The greater part of the volume under consideration is by the first of the two authors whose names appear on the title-page, Mr. Van Dyke merely contributing a small section—considerably less than 100 pages—on the game-birds of the Pacific coast.

Throughout the work, the authors appear to have hit the happy mean between a strictly scientific treatise and a purely sporting manual, each species being carefully described in accurate and, at the same time, popular language, while the rest of the space devoted to each is a pleasantly blended mixture of sport and natural history, enlivened by a number of racy anecdotes. Mr. Sandys evidently loves his subject, and, being himself an enthusiastic sportsman with a strong bias towards natural history and a delightful style of writing, it is little wonder that he has succeeded in producing a most interesting book. The volume commences with the "bob-white," the so-called American quail, and embraces all the species and varieties which can be classed as game-birds up to, and inclusive of, such a magnificent bird as the wild turkey, which the author calls the king of wild birds. The scientific nomenclature is thoroughly up-to-date—perhaps, indeed, almost too much so, as Mr. Sandys follows those authorities who consider it necessary to separate the American woodcock generically from its European relative. A notable instance of the extreme degree of refinement to which modern American zoology is carried occurs in the case of the plumed partridge, which is stated to differ from the typical *Oreortyx pictus* chiefly by its predilection for a mountain habitat.

As an example of Mr. Sandys's powers of accurate observation and induction, we may refer to his account, p. 223, of the resemblance of the ptarmigan in winter dress to its surroundings. After mentioning that every projection above clean snow is apt to cast a more or less decided shadow and thus cause a darker spot, he observes that the black tail of the crouching ptarmigan so closely imitates this effect that the intelligent observer cannot fail to detect Nature's purpose in the one peculiar mark. In such a brief notice as our space allows, we cannot quote further, and can only say that the authors and the artists have combined to produce a most attractive and interesting little volume. R. L.

Wild Fruits of the Country Side. Figured and described by F. Edward Hulme, F.L.S., F.S.A. Pp. viii + 259; with thirty-six coloured plates by the author. (London: Hutchinson and Co., 1902.) Price 12*s.* 6*d.* net.

THIS work forms one of the "Woburn Series of Natural History," published under the auspices of the Duke of Bedford, and intended, as His Grace's preface shows, to supply to those who, from various circumstances, cannot devote themselves to the scientific study of natural history, some knowledge of the processes and products of Nature in a form at once easily assimilated and scientifically accurate.

The author himself amplifies this statement of his editor, and declares "Our purpose to be a very simple one, to deal with the principal typical forms that one may reasonably expect to meet with during a country sojourn, and to deal with them in the simplest way—caring but little to send our readers to the dictionary in a wild quest for six-syllabled words of weird appearance, but caring much if the result of the perusal of our pages be to so far interest them as to send them to seek for themselves in the great Book of Nature."

The class of people for whom this book is intended is further defined as including those who need to be told that "a privet berry and an acorn are distinguishable one from the other, that a beech nut and a blackberry are not so identical in form and colour but that practice and observation will enable us to tell which is which."

A much less pretentious book would surely have answered the purpose as well as this handsome volume. The nature of the text may be inferred from what has been said—it contains much pleasant gossip, but little information, and no pains have been taken to correlate or classify what there is.

The illustrations are pretty and well executed, but scrappy and wanting in detail; for instance, a fragment of the common yew and a similar morsel of the dogwood (Cornus) are placed together on the same plate without any particular reason and with no details. We can only suppose this has been done for the benefit of those who cannot distinguish a beech nut from a blackberry. The table of contents of the three chapters into which the book is divided is very full, but very unsystematic. The index is copious, but displays the same absence of method; for instance, the first entry runs thus, "Abnormal Chestnut Cluster, 128," but there is no corresponding reference under Chestnut or under Cluster, both more important words for the user of the index than that chosen to direct his research. In fine, we can but regret the expenditure of so much time, labour and money which might with so much greater profit have been bestowed on a work of a different character.

A word of praise is due to the printer and publisher, for paper, typography and illustrations (so far as they go) are all good.

Einführung in die Theorie der Doppelbrechung. By Heinrich Greinacher. Pp. 64; numerous figures. (Leipzig: Von Veit and Co., 1902.) Price M. 1.20.

THIS is a simple account of some of the leading phenomena of double refraction considered by the help of geometric methods. These are of the simplest type, no attempt being made to give rigorous proofs where any difficulty would be encountered. The booklet can, therefore, only be recommended to those who are unable to grasp the theory as usually given, but desire some explanation of the phenomena which they have met with experimentally. They are presumably acquainted with such phenomena, as no diagrams of the effects described are provided; these might be added with great advantage. The description is lucid, but meagre. If the attack were concentrated on the ellipsoid of elasticity and the wave surface instead of spread out over four surfaces, greater success would be achieved. A. W. P.

Physical Geography. By Margery A. Reid, B.Sc. With maps and illustrations by Bertha Reid. Pp. iv + 148. (London: Allman and Son, Ltd.) Price 2*s.* 6*d.*

THOUGH this little book contains so few pages, it is divided into twenty-four chapters, in each of which new subjects are introduced. The reader is thus hurried from one subject to another without explanation enough to make the work intelligible. Rivers and glaciers are described in a little more than two pages. Rain receives scarcely any attention and the rain-gauge is not described at all When the author seriously attempts an explanation she is successful, but the limited space has prevented her from doing justice to herself or her subject. Especially in the descriptions of experiments is the guidance insufficient. For instance, we read on p. 35, "Submerge a shoot of watercress in water. Bubbles of gas collect on it; if some of these be tested as they ascend through the water, they are found to be oxygen." How to catch one of these bubbles and test it under water would puzzle older students than those for whom the book is intended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Hydrography of the Faeroe-Shetland Channel.

IN that portion of the programme of international investigation of the North Sea (as finally drawn up by the conference at Copenhagen last July) which provides for a coordinated series of hydrographic cruises at intervals of three months, it falls to Scotland to investigate the Faeroe-Shetland Channel and adjacent waters. It was important that the work should be begun as soon as possible, and especially so in order that the sea-temperatures, &c., should not go unrecorded in this abnormal season; but it would have been impossible to begin at so short notice had not Dr. Hjort, the director of the Norwegian investigation, helped by the loan of apparatus and by permitting his hydrographic assistant, Mr. Helland-Hansen, to come over and inaugurate the work. The Admiralty gave the use of H.M.S. *Jackal*; Lieutenant and Commander Sharpe and Mr. Helland-Hansen were conjointly responsible for the observations, and the report will be drawn up by Mr. Helland-Hansen, who has sent me the preliminary account which follows. The *Jackal's* course lay from the Moray Firth to Lerwick, thence in a north-easterly direction nearly to the Norwegian coast, then west to the Faeroes, thence to Fair Isle and out into the North Sea again; and it was so planned as to give, over each of the more important areas, double and approximately parallel lines of observations. Between August 25 and September 1, hydrographic observations were taken at twenty-six stations, and in addition surface-temperatures were taken every hour. A small number of plankton samples was collected also, but not to the extent that will be done on future cruises.

D'ARCY W. THOMPSON.

The Cruise of H.M.S. "Jackal," August, 1902.

The following short account is only a preliminary one and is given with some reservation, as the time has not yet permitted to draw the final results. In some weeks, however, we shall know the results of the investigations of the Norwegian fishery steamer *Michael Sars* from the neighbouring seas during the same period, and then we shall be able to work out the material from the *Jackal* very completely.

The best result from the *Jackal* expedition is, perhaps, that for the time in question we shall be able partially to solve the problem, equally important to hydrographers and biologists, of *the quantity of Atlantic water entering the North Sea and the Norwegian Sea*. Many years ago, and by different investigators, it was demonstrated that a large quantity of Atlantic water moved to the north between the Faeroes and Shetland (the Gulf Stream), and also that Atlantic water to the north and north-east of Scotland flowed in a south-westerly direction into the North Sea. Now we have undoubtedly found some unknown details of great importance.

(1) *The Gulf Stream is in the Faeroe-Shetland Channel divided from beneath by a deep wedge of cold and less salt water coming from the north.* The influence of this cold water is traced even to the surface. Thus we have really two parallel branches of the Gulf Stream from the Faeroe-Shetland Channel to the north. This fact may be shown by the following table. Station xii. (61° 2′ N., 1° 10′ W.) is situated near Shetland, and station xvi. (61° 47′ N., 6° 4′ W.) near the Faeroes. The temperatures and salinities at, for instance, 300 metres' depths—stations xiii. (61° 12′ N., 2° 5′ W.), xiv. (61° 25′, 3° 24′ W.) and xv. (61° 35′ N., 4° 39′ W.)—are very typical.

Stations.

Depth in metres.	xii.		xiii.		xiv.		xv.		xvi.	
	Tem. °C.	Salin.	Tem. °C.	Salin.	Tem. °C.	Salin.	Tem. C.	Salin.	Tem. C.	Salin.
0	11·3	35·33	11·2	35·31	9·5	34·96	8·9	34·98	9·2	35·19
40	10·8	35·32	10·7	35·31	10·0	35·07	8·4	35·11	8·7	35·17
100	9·4	35·32	9·4	35·31	*ca.* 8·5	*ca.* 35·14	8·2	35·20	8·5	35·19
200	Bottom		8·9	35·32	6·3	35·10	7·7	35·20	Bottom	
300			8·5	35·32	3·6	34·97	6·9	35·14		
400							6·4	35·09		
500			6·6	35·17	1·2	34·95				

As the cold water from the north and the warm water from the south have very different influences upon organic life, the discovery of such a division of the Gulf Stream will probably be of importance in understanding the distribution of the organisms.

(2) *In August comparatively little Atlantic water enters the North Sea in the surface between Scotland and Shetland.* The influx of Atlantic water chiefly takes place *close to the coast of Scotland*, at a distance of about twenty to forty nautical miles away from the coast. [Further away, at about eighty miles' distance, the surface-water seems to move in a northerly direction. This cannot be certainly decided, however, until a minute examination of the hydrodynamic conditions has taken place.]

(3) *Another branch of Gulf Stream-water enters the North Sea between Shetland and Norway.*

(4) In the north-western part of the North Sea we find *at the bottom* (below thirty to forty fathoms from the surface) *a layer of remarkably cold and salt water*; it is much salter than the surface-water. It is too salt to be Arctic water and too cold to be summer water from the Atlantic Ocean. I think it probable that this bottom layer consists of Atlantic water that has been at the surface in winter time. Our hydrographical observations, then, seem to indicate that *the influx of Atlantic water into the North Sea in winter time takes place to a much greater extent than in summer time.* To find the laws of the variations of this influx, however, we must have autumn and winter observations.

The regions where the *Jackal* collected her material this year were previously incompletely explored. I have only now had an opportunity to compare our observations with those found in Mr. H. N. Dickson's excellent paper on "The Circulation of the Surface-Waters of the North Atlantic Ocean" (published 1901). Unfortunately, Mr. Dickson's observations are limited to the surface. It seems as if the influx of the cold water from the north and the east Icelandic Polar current this year were much stronger than in, *e.g.*, 1896. In the western part of the channel, the surface-temperatures this year were about 1°–1½° C. lower than in 1896, and the Gulf Stream seems to have been narrower. This may probably be connected with the unusually cold weather of this year.

B. HELLAND-HANSEN.

Matriculation Requirements in Scottish Universities.

IN reference to a remark made in my address published in NATURE last week, Prof. A. Gray tells me that matriculation in the Scottish universities is no longer the simple matter it was in my time. Before entering on his qualifying course of study, every candidate for a degree in arts or science must now pass a preliminary examination.

The Neglect of Anthropology in British Universities.

THE recent publication in NATURE (August 28, p. 430) of an abstract of Prof. Haddon's presidential address to the Anthropological Institute, affords an opportunity of bringing before the scientific public, by way of contrast, a concise statement of what is being at present done in Britain to forward anthropological science.

Of all the universities in Britain, two only attempt systematic teaching in this subject, viz. Oxford and Cambridge, while in a third, viz. Aberdeen, there has existed since 1899 a society having for its object the promotion of anatomical and anthropological research. In Oxford there is a poorly paid professorship of anthropology, but in Cambridge even this scanty recognition is not vouchsafed to the subject, for in that University there are two lectureships of but 50*l*. a year each, established in 1899 and 1900 respectively for five years. One of these lectureships is devoted to physical anthropology and is attached to the School of Human Anatomy. The other, held by Prof. Haddon himself, is for ethnology, and covers the wide field of all relating to the industries, customs and beliefs of primitive peoples, now in many cases approaching extinction, and the loss by disinterestedness of their primitive customs and unwritten records. It cannot be expected that any real advance in these branches of science can be made in Britain while they are so pitifully starved, and while the men holding mere precarious appointments are not deemed worthy of their hire.

Now that the war is over, cannot some appeal be made to remedy this state of things? Is it too much to hope that a chair for ethnology might be endowed by private benefaction for the new teaching University of London, or at least that subscriptions might be secured sufficient to place the existing lectureships in Cambridge on a sounder and more satisfactory basis?

ANTHROPOTAMIST.

Phosphorus versus Lime in Plant Ash.

THAT in the mineral constituents of leaves a strong proportion of lime is an obstacle to the presence of a considerable quantity of potass has been recognised as a feature of calcifugous species of plants. It has been sought, indeed, to explain, apparently on this ground alone, the existence of special plants which shun lime soils, or at least to account for the difference between their habitat and that of calcicolous species. A certain proportion of lime in the soil, say about 12 per cent. carbonate, is sufficient for the needs of a certain number of calcicolous species and banishes the calcifugous species from it. If, however, we carefully examine the ash constituents of the leaves of herbs growing and seeding in a soil (such as here in this valley) with only about 1 per cent. lime (CaO) in its finer particles, we recognise a large ratio both of potass and of lime, as the annexed table will attest.

Leaves of	Date.	Percentage of Ash.	Constituents of the Ash. Soluble Salts.	CaO.	P_2O_5.
Hawkweed	July 15	12·6	24·7	28·4	4·3
Figwort	,, 24	8·9	31·7	24·7	8·35
Bracken (stem)	,, 24	—	63·8	4·1	3·04
Cranesbill (lamina)	,, 27	7·5	38·3	24·9	9·5
Hazel	,, 29	6·3	18	30·4	7·7
Rowan	,, 31	6	38·5	23	5·6
Dock	Aug. 1	11·7	43·4	20	6·3
Water Flag	,, 5	8·7	42·2	29	6
Sycamore	,, 5	10·5	33·6	25·7	4·7
Great Knapweed	,, 12	10	37·1	29·4	3·6
Ragwort	,, 19	12·2	44·5	23·7	5·15
Foxglove	,, 21	9·1	40·7	25·3	5
Heather (whole plant)	Sept. 19	2·2	25	16·3	7·3
Sycamore fruit	,, 24	5·5	37	25·7	8

These figures are taken from my own analyses, the percentages being calculated on the crude ash minus charcoal. The sphere of experimental observation is, perhaps, too narrow or restricted, but a suspicion is awakened by the results that the need for phosphorus is a direct or indirect agent operative in the case. That is to say, a strong proportion of lime in the ash seems rather an auxiliary or accompaniment than an obstacle to a strong proportion of potass (as computed by the soluble salts). On the other hand, we see a rough approximation to an inverse ratio between the lime and the phosphorus, *i.e.* roughly 28 or 29 per cent. of lime with 3 or 4 P_2O_5, and 23 or 24 lime with 8 or 9 P_2O_5; and where this does not prevail, the whole percentage of ash is below the average (as in water flag and the woody plants). That a poor yield of certain plants on calcareous soils appears to be due to the effect of the lime in preventing the assimilation of phosphorus is a result of the experiments of MM. Dehérain and Demoussy. Moreover, it is known that the ash of seeds, which is invariably very rich in phosphorus, contains also a comparatively very small proportion of lime. It would seem, therefore, to be legitimate to conclude that a certain proportion of lime in the soil (say 3 or 4 per cent.) is inimical to the life of certain plants which require a definite amount of phosphoric acid for the healthy performance of their physiological functions. The fact that some plants will grow, but not flourish or propagate, in certain localities or habitats is a pretty certain indication that a sufficient amount of phosphorus is not available to the seed for purposes of germination and development. The analyses would seem to indicate that a too liberal supply of lime is the preventative agent in the case.

P. Q. KEEGAN.

Patterdale, Westmorland.

ALUMINIUM AND ITS ALLOYS.

THE electrolytic process for the extraction of aluminium, which was patented in 1887 by Héroult in Europe and by Hall in America, has resulted in such a great diminution in the cost of production that the price of the metal has fallen from about twenty shillings to one shilling a pound. It is not surprising that, in the early days of the electrolytic industry, this circumstance, combined with the many very valuable properties of aluminium, caused extravagant hopes for its future to be raised.

The experience that has been gained in the past five or ten years has enabled us to form a truer estimate of the value of the metal, though it would be difficult to say even now to how great an industrial importance it may ultimately develop. A very good idea of the present position and prospects of the industry may be obtained from two papers recently published in the *Journal* of the Institution of Electrical Engineers.[1] The first of these, by Prof. E. Wilson, gives the results of an elaborate series of tests of the physical properties of a number of aluminium alloys; we shall have occasion to refer to this paper later. The second paper is by Mr. W. Murray Morrison, and contains a description of the British Aluminium Company's works at Foyers and an account of the applications of the metal, its use as an electrical conductor being considered at some length. We are enabled by the courtesy of the British Aluminium Company to give an illustration showing the turbo-generators in the power-house at Foyers.

The Hall and Héroult processes for the electrolytic extraction of aluminium are practically identical and are too well known to need lengthy description. The aluminium is obtained as the result of the electrolysis of alumina dissolved in melted cryolite ($6NaF.Al_2F_6$). The electrolysis is carried out in a carbon-lined crucible, at the bottom of which the separated metal collects, the liberated oxygen combining with the carbon of the anode and passing off ultimately as carbon dioxide. It is interesting to note that, whereas the specific gravity of solid aluminium is less than that of solid cryolite, in the fused condition this order is reversed; but for this the process in its present form would be unworkable. Some figures showing the cost of production by the Héroult process are given by Mr. Blount in his "Practical Electrochemistry," as follows:—

Cost of power	... 2·2	pence per lb. of aluminium.
Cost of alumina	... 4·0	,, ,, ,,
Cost of electrodes	... 2·0	,, ,, ,,
Cost of labour, &c.	... 2·0	,, ,, ,,
Total cost	... 10·2	,, ,, ,,

It is probable that this estimate is somewhat high, but it is sufficient to show that the cost of power is a very important item, which explains the necessity for the use of water-power. The cost of power per lb. is higher than in any other electrolytic manufacture; it forms, it will be seen, about one-fifth of the total cost; in the manufacture of calcium carbide, another electrochemical industry requiring cheap power, the ratio of cost of power to total cost is about 1 to 7·5.

The product of the electrolytic furnace is very pure. According to Mr. Morrison, commercial aluminium is 99·5 to 99·6 per cent. pure, the impurities being iron (about 0·25 per cent.) and silicon (about 0·17 per cent.). A sample of pure commercial aluminium analysed by Prof. Wilson contained 0·31 per cent. Fe and 0·14 per cent. Si, which agrees pretty closely with Mr. Morrison's figures.

[1] "The Physical Properties of certain Aluminium Alloys, and some Notes on Aluminium Conductors," by Prof. E. Wilson. (*Journal* I.E.E., vol. xxxi. p. 321.) "Aluminium: Notes on its Production, Properties and Use," by W. Murray Morrison. (*Ibid.* p. 400.)

This standard of purity has only been gradually attained, and we may hope for further improvement. The purity is a matter of importance, as it affects the value of the metal as an electrical conductor in two ways, for impurities not only lower the conductivity, but also increase the liability to atmospheric corrosion. The evidence as to the power of aluminium to withstand atmospheric influences, especially in towns or places where the air is bad, is somewhat conflicting, but on the whole it seems that the metal is fairly satisfactory in this respect. The thin film of oxide which immediately forms on the surface of the metal in air acts as a protective coating. Mr. Morrison quotes an interesting illustration of the tenacity of this oxide film; if the metal is cast into a mould and allowed to overflow, the film of oxide adhering to the molten metal that has run over acts as a syphon tube, and will syphon out a considerable quantity of the aluminium.

FIG. 1.—The British Aluminium Company's Power-house at Foyers.

The two most marked characteristics of aluminium, on which its principal applications depend, are its high affinity for oxygen and its low specific gravity. The former of these properties causes aluminium to play a part of considerable importance in the metallurgy of other metals. Thus in the casting of steel, iron, brass, &c., the addition of a small quantity, two to five pounds per ton, of aluminium is found greatly to improve the finished casting; the aluminium, by combining with the occluded gases, reduces the blowholes and renders the metal being cast more fluid and ultimately more homogeneous. Though the actual quantity used in this way is but a small percentage of the metal to which it is added, the total consumption of aluminium for this purpose is very large. A second use for aluminium depending on the same principle has been devised by Dr. Goldschmidt for producing high temperatures, and has been applied to the welding of iron rails, pipes and so forth. A mixture of iron oxide and finely divided aluminium is used, and is ignited by means of a magnesium ribbon; a very high temperature is immediately reached by the oxidation of the aluminium at the expense of the oxygen of the iron oxide. This process, having been only lately introduced, has not yet become of much commercial importance, but is full of promise.

The extremely low specific gravity (2·6) of aluminium has naturally resulted in its use in cases in which weight is a drawback. Thus in naval and military equipments, in motor-car construction and like applications, the metal already finds considerable and increasing employment. For cooking utensils the use of aluminium is steadily increasing; the metal is eminently suited for this purpose, as, apart from its lightness, it is a good conductor of heat, is not liable to deteriorate in use and gives rise, if dissolved, to perfectly harmless compounds. Applications of this kind may seem small individually, but in the aggregate they constitute no mean field for the metal to capture.

The chief drawback to aluminium is its low tensile strength, which, for the cast metal, is only from five to eight tons per square inch; but for this weakness its utility would be enormously increased. A certain amount of improvement can be effected by alloying a small quantity, generally less than 10 per cent., of some other metal, such as nickel or copper, with the aluminium. The specific gravity of these alloys is only slightly higher than that of the metal itself, but the tensile strength may be made two or three times as great. Exceedingly valuable data relating to a number of these light alloys are contained in the paper by Prof. Wilson to which reference has been made above. It is impossible to enter at all fully into the results obtained by Prof. Wilson, as the paper is itself so condensed as to be little more than a summary, but a few of the more interesting conclusions may be briefly tabulated. In the accompanying table is shown approximately the effect of alloying different metals on the conductivity, specific gravity and strength of aluminium.

Aluminium is now finding considerable employment as a substitute for copper as an electrical conductor, especially in America, where it is used to a large extent in connection with the transmission of power over long distances. One of the most important of these installations is the transmission of 12,000 h.p. from the Snoqualmie Falls to Seattle and Tacoma, a distance of more than forty miles. In this scheme an alloy of aluminium with 1½ per cent. of copper has been used, the lightness

Aluminium.	Principal Impurity.	Other impurities.	Specific Gravity.	Conductivity.	Limit of Elasticity: lb. per sq. in.	Breaking Load: lb. per sq. in.
99.5 per cent.	Commercial aluminium	Fe (0·31), Si (0·14)	2·715	61·5	19,376	28,200
98–97 ,,	Copper, 1·6–2·6 per cent.	Fe (0·4), Si (0·4)	2·75	51	33,000	41,000
98–97 ,,	Zinc, 1·2–2·4 ,,	Fe (0·4), Si (0·43), Cu (0·2)	2·74	56	20,500	28,000

and strength of this alloy enabling spans of 150 feet to be made with safety. A great saving in the number of poles is thus effected, which is one of the principal advantages gained. Numerous other important transmission schemes might be quoted in which aluminium is used, or in which it has been decided to use it. As has been just pointed out, the use of aluminium effects a great saving in the number of poles required; it also involves dealing with a much smaller weight of conductor, and is, finally, cheaper than copper. In round numbers, for equal conductivity, the section of an aluminium cable is one and a half times that of a copper one, the weight is half and the tensile strength three-quarters. It is the decreased weight which, in spite of the smaller tensile strength, allows longer spans to be used, and this effect can be made more marked by the use of a suitable alloy possessing increased strength without much diminished conductivity or much higher specific gravity. Mr. Morrison gives an interesting table showing the variation, according to the price of copper, in the price per lb. that can be paid for aluminium for equal conductivity and equal cost. From this it appears that with copper at its present price of about tenpence per lb., twenty-one pence per lb. could be paid for aluminium, which is two or three pence above its market price, showing that aluminium conductors are cheaper.

It is to be noted that the above remarks apply only to bare conductors. Where insulated cables are needed for low-tension work the increased diameter of an aluminium conductor involves increased cost in insulating material; moreover, with lead-covered cables the increased weight of the lead would almost, if not quite, cancel the decrease in weight gained by substituting aluminium for copper. For high-tension cables it is possible that aluminium may in some cases be cheaper than copper. Thus in a paper by Mr. M. O'Gorman[1] it is shown that increasing the diameter of the conductor may produce such a diminution in the depth of insulation necessary as to lessen the total price; in such circumstances a tubular copper conductor, or an aluminium conductor, could be used with advantage. There seems, therefore, a possibility that aluminium may some day successfully invade the field of insulated cables, hitherto regarded as peculiarly the property of copper.

M. S.

RECENT WORKS ON SYSTEMATIC BOTANY IN GERMANY.

It was in the year 1887 that, following on the publisher's announcement, the first parts of "Die natürlichen Pflanzenfamilien" appeared under the joint editorship of Drs. Engler and Prantl. The announcement does not seem to have attracted much attention, as there was no mention of it in many botanical journals until several numbers following each other rapidly came under notice. Strange as it may seem, De Bary's name does not appear as one of the collaborators, nor did he have any share in the work. His remarks, therefore, as set forth in *Die Botanische Zeitung* in October, 1887, besides providing a criticism of the general scheme, also enable one to form an idea of the attitude displayed towards the undertaking.

He says, "the object is to present by means of illustrations and descriptions a corporate picture of the plant world which shall be strictly scientific and at the same time generally intelligible. Under each family, and for each genus of that family, mention will be made of any points that call for description or that have a practical bearing."

That there was some uncertainty as to its successful completion may be gathered from what he says later, after congratulating editor and publisher:—

"If the book is only carried through as it has been started, then it will have no equal . . . since it gives information shortly and objectively, not in the abstruse and learned manner of Bentham and Hooker, nor yet in the form of the subjectively learned monograph touched up with popular varnish which characterises the otherwise life-like history of plants by Baillon." Undoubtedly the terse and vigorous descriptions, the careful choice of matter, and the wealth of illustration which elicited favourable comment for the earlier numbers have, on the whole, been consistently maintained. Now that the work is almost completed, and as one looks back on the enormous labour entailed, congratulations may again be offered to Dr. Engler, who has been the sole editor since Dr. Prantl died in 1893.

The responsibility of such a vast undertaking might well be sufficient, but in the year 1900 Dr. Engler announced the publication of a new work, "Das Pflanzenreich"—adopting the title suggested by De Bary—which will amplify the information given in "Die natürlichen Pflanzenfamilien." As Dr. Engler announces in his introduction, "Das Pflanzenreich" is not a revised edition of "Die natürlichen Pflanzenfamilien," for appendices to the latter will continue to appear from time to time, and whereas "Die Pflanzenfamilien" gives a complete account of the orders and genera, but only enumerates a few species, "Das Pflanzenreich" will furnish a full and comparative account of all authenticated species.

Eleven parts have already been issued—"Musaceæ," by K. Schumann; "Typhaceæ and Sparganiaceæ," by P. Graebner; "Pandanaceæ," by O. Warburg; "Monimiaceæ," by J. Perkins and E. Gilg; "Rafflesiaceæ and Hydnoraceæ," by H. Graf zu Solms Laubach; "Symplocaceæ," by A. Brand; "Naiadaceæ," by A. B. Rendle; "Aceraceæ," by F. Pax; "Myrsinaceæ," by C. Mez; "Tropæolaceæ," by Fr. Buchenau; and "Marantaceæ," by K. Schumann.

As regards the general arrangement, the citation of important literature and the review of the main characters of the order are similar to the method adopted in "Die Pflanzenfamilien," and, together with a certain number of illustrations, will be more or less the same. But, apart from new facts which may be added, it will be observed that the orders are not necessarily taken up by the same authors in the two works. English botanists may be

[1] "Insulation on Cables," by Mervyn O'Gorman. (*Journal* of the Institution of Electrical Engineers, vol. xxv. p. 608.)

allowed to express their satisfaction with the inclusion of one of our ablest systematic workers.

The key and description for each species are given in Latin, in order that, as the author remarks, they may be available to the botanists of all nations. The parts will not be issued in any particular sequence, the only proviso being that no order will be forthcoming until at least twelve years have elapsed since it was treated either in "Die Pflanzenfamilien" or in De Candolle's "Suites au Prodromus." Each part dealing with one order will be complete in itself and will contain an index.

Apart from the memoirs incorporated in these two works, many of the studies in systematic botany, the results of which have been published in Germany within recent years, have been controlled more or less by Dr. Engler in his position as director of the Botanical Museum in Berlin. The "Flora of Africa," which has reached the twenty-third instalment, represents mainly the investigations of workers in the Berlin Museum. One of the assistants, Dr. L. Diels, has written an able memoir on the "Flora von Central China." It is especially noticeable how distant and comparatively unknown are many of the countries in which the herbaria have been formed which are finding their way to the museums in Germany. The same spirit of unflagging energy which has made famous the names of many German collectors, whose object has been to acquire fame by sending home flowers previously unknown, may here be found, but the incentive is merely scientific enthusiasm.

NOTES.

THE Huxley Memorial Tablet represented in the accompanying illustration was unveiled at the Ealing Public Library on Thursday last by the Mayor of Ealing, Alderman H. C. Green. The inscription upon the tablet is, "The Right Honourable Thomas Henry Huxley. Born at Ealing, 4th May, 1825. Died at Eastbourne, 29th June, 1895. 'Try to learn something about

everything, and everything about something." The whole memorial was designed by Mr. Frank Bowcher, with the assistance of Prof. G. B. Howes, F.R.S. The background of the tablet is "Dove" marble; the frame, top row of lettering, wreaths and medallion are bronze; the rest of the inscription is in incised gilt letters. The movement to establish this memorial originated with Mr. B. B. Woodward, who brought it before the Ealing Natural Science Society, and a committee was formed with him as hon. secretary. Altogether about eighty subscriptions were received, mainly from Ealing residents, hence the tablet shows that the memory of Huxley is cherished at his birthplace. Among those present at Thursday's ceremony, in addition to the Mayor, were Prof. G. Henslow, Mrs. T. H. Huxley, Mr. and Mrs. Leonard Huxley, Mr. L. Fletcher, F.R.S., Mr. B. B. Woodward, and Mr. F. E. Beddard, F.R.S. (representing the Zoological Society of London). Letters regretting inability to attend were read from Prof. Howes and Lord George Hamilton. Prof. Henslow gave a short address, in the course of which he related some personal reminiscences of Huxley; and the Mayor of Ealing afterwards unveiled the tablet. The accompanying photograph having been taken before the tablet was erected, an error of the mason's, undetected at the time, but since corrected, gives the date of Huxley's death as the 25th instead of the 29th of June, 1895.

WE regret to see the announcement of the death of the Rev. Dr. Wiltshire, formerly professor of geology and mineralogy at King's College, London.

THE opening meeting of the Institution of Electrical Engineers is fixed for Thursday, November 13, when the premiums awarded for papers read or published during the session 1901–1902 will be presented, and the president, Mr. James Swinburne, will deliver his inaugural address.

AT the recent conference of Colonial Premiers, a resolution in favour of the metric system of weights and measures was adopted. Referring to this action, Mr. Chamberlain has informed a correspondent that he fully recognises the importance of the matter, and is in correspondence with the Colonial Governments and the Board of Trade on the subject.

IN reply to a question in the House of Commons on Thursday last, Mr. Austen Chamberlain said:—A new cable has been laid to Belgium, and telephonic communication between London and Brussels will be opened as soon as the necessary arrangements can be completed. The establishment of communication between London and Berlin is not at present feasible.

ENERGETIC measures are being adopted at Odessa to prevent the spread of plague from the cases which have occurred there. The outbreak of the disease in May of this year is attributed to the presence of rats, which have carried the means of infection since the last case of plague was treated in Odessa in November, 1901. Systematic efforts are therefore being made to destroy the colonies of rats and carry out strict sanitary regulations.

THE chief members of the Scottish Antarctic Expedition about to start for the South Polar regions were entertained to dinner in Edinburgh on Thursday last by the president of the Royal Scottish Geographical Society, Sir John Murray. Replying to the toast proposing success to the expedition, Mr. W. S. Bruce, the leader, remarked that the work undertaken would be supplementary to that of the three expeditions already in the Antarctic, and would be largely oceanographical. The Scottish area of activity would be around that part of the Antarctic where Sir James Ross, sixty years ago, took one sounding, attaining a depth of 4000 fathoms without reaching bottom.

THE Home Secretary has appointed a committee to inquire into the use of electricity in mines and the dangers attending it, and to report what measures should be adopted in the interests of safety by the establishment of special rules or otherwise. The committee consists of Mr. H. H. S. Cunynghame, C.B. (chairman), Mr. Charles Fenwick, M.P., Mr. Archibald Hood, past president of the Mining Association of Great Britain, Mr. James Swinburne, president of the Institution of Electrical

Engineers, and Mr. W. N. Atkinson and Mr. A. H. Stokes, H.M. Inspectors of Mines. The secretary of the committee is Captain A. Desborough, H.M. Inspector of Explosives.

THE Berlin correspondent of the *Standard* announces that the International Conference on Wireless Telegraphy will be held in Berlin about the end of March or the beginning of April next. England, the United States, France, Austria-Hungary, Italy and Russia have all responded to the invitation from Germany, and have intimated that they will accept an invitation to a conference in Berlin on condition that the programme is fixed beforehand and sent with the invitation. It is hoped to draw up a programme shortly, if possible before the end of February.

THE Paris correspondent of the *Times* reports that investigations by the Lacroix expedition to Martinique have shown that the immense opening on the south-west side of the crest of Mont Pelée has grown to formidable dimensions, and the White River is choked near its source. The dangerous portion of the mountain is the south-west slope.

MR. A. W. CLAYDEN writes to direct attention to the close resemblance between recent sunset effects and those which followed the eruption of Krakatoa in 1883. At Exeter, on Friday last, he observed very high cirrus clouds which passed through the various shades of yellow and red to grey, and then changed to brown, golden yellow and vivid crimson. The double series was as pronounced as in any of the sunsets of 1883. On Sunday evening, faint cirro-stratus became visible just before sunset, exactly resembling those seen at sunrise and sunset in 1883. The afterglow on Tuesday was richer in tone than any Mr. Clayden remembers since the Krakatoa effects. It will be remembered that similar observations of remarkable sunsets since the West Indian eruptions of May last have been made elsewhere and recorded in these columns (see pp. 199, 221, 294, 390 and 540).

THE third annual Huxley memorial lecture was delivered at the Anthropological Institute on October 21 by Prof. D. J. Cunningham, F.R.S. The subject was "Right-handedness and Left-brainedness," and Prof. Cunningham referred to the general interest which it presents to all students of anthropology. So far as available evidence goes, it seems probable that right-handedness was a characteristic of man at a very early period in his evolution. It is an inherited quality in the same sense that the potential power of articulate speech in man, and of song in the bird, are inherited possessions. Investigation shows that right-handedness is due to a transmitted functional pre-eminence of the left brain, and this factor prevents an oscillation of the condition from one side to the other in those curious cases in which the right and left sides of the body are reversed and the thoracic and abdominal viscera transposed. The greater part, if not the whole, of the motor incitations which lead to articulate speech go out from the speech centre which resides in the left cerebral hemisphere. In left-handed people, the predominance of the right cerebral hemisphere is accentuated by the transference to it of the active speech centre. Left-handed people, therefore, speak from the right brain. Prof. Cunningham concluded by pointing out that before definite conclusions could be arrived at upon many aspects of the subject, it is necessary that detailed observations should be made of the development and growth-changes of the cerebral cortex of the ape and man.

THE International Conference on Tuberculosis was held in Berlin on October 22–26, about four hundred members being present at the opening ceremony. At the final meeting, the following officers were elected for the international union against tuberculosis:—President, Prof. Brouardel, Paris; vice-presidents, Prof. Andword, Christiania; Sir William Broadbent, London; Dr. Dewez, Mons; Prof. Espina y Cayo, Madrid; Prof. von Leyden, Berlin; Prof. Linroth, Stockholm; Prof. Margliano, Genoa; Prof. Schirwinsky, Moscow; and Prof. von Schrötter, Vienna. The executive committee consists of Dr. Althoff (president); Prof. Fraenkel, Berlin; Dr. Calmette, Lille; Dr. Chyzer, Budapest; Dr. Noerdam, Copenhagen; and Dr. Raw, Liverpool; with Dr. Pannwitz, Berlin, as secretary.

FROM a note in the *Times* we learn that a resolution of the Government of India on the report of the Imperial Bacteriologist for the past official year describes the chief work of the department for the year as the testing and production of the rinderpest serum. The experiments were directed to improving its protective quality and perfecting the process of manufacture. The results obtained at Jacobabad, Madras and Rangoon showed that the initial protective value of sera is materially diminished by exposure to high temperatures. Experiments relating to anthrax are said to have been brought to a successful issue by the discovery of a protective serum, and researches have been prosecuted into other animal diseases. A scheme recently sanctioned for enlarging the laboratory will, it is hoped, lead to the production of 100,000 doses of the serum per annum, while the plan for training veterinary assistants at the laboratory in the inoculation of cattle against rinderpest has been successful. It has been decided to discontinue the issue of fungus tubes for exterminating locusts, the results not having been successful in any of the provinces; meanwhile, investigations and experiments on the subject will be conducted in the agricultural department as well as by the bacteriologist.

A LIST of the earthquakes and volcanic eruptions recorded from April 10 to September 23 of this year has been compiled by the *New York Times* and is reprinted in the *Scientific American* of October 11. Serious disturbances of the earth's crust have occurred on the following dates in various parts of the world:—April 10, 18; May 3, 7, 8, 12, 13, 15, 18, 20, 21, 24, 28, 30, 31; June 2, 4, 6, 8, 9, 14, 15, 19, 20, 21, 22, 24; July 1, 7, 8, 9, 10, 11, 12, 17, 27; August 13, 14, 15, 25, 27, 30; September 1, 6, 8, 9, 16, 17, 22, 23. Reports have since been received of disturbances on September 25, October 4, 6 and 16–25. With reference to the last of these records, when both Mont Pelée and the Soufrière of St. Vincent were in eruption, it is perhaps worth remark that a postcard posted at Greussen was received from Herr Nobbe on October 16 predicting that disturbances would occur on October 17 and 18, not only at Martinique and St. Vincent, but also in Europe and America.

THE Odessa correspondent of the *Standard* quotes from the *Turkestan Gazette* some further details with regard to the Kashgar earthquake of August 22. It appears that the earthquake was far more disastrous than was supposed from the first accounts. The populous settlement of Nijni-Artish, lying to the north-east of Kashgar, was practically razed, many of the houses were wholly or partially engulfed in huge fissures, and 1700 persons perished. In Kashgar itself and in the immediate neighbourhood, the earthquake was less destructive to property, but 600 persons were killed. The village of Besh-Kerim, consisting of eighty houses, was entirely destroyed, with the whole of its inhabitants, in number about 550. The total loss of life is estimated at a little above 3000. Undulations of the surface, like sea-waves, were observed in the Chatar-Kula Hills; and the wooded banks of the Scharikhanskaia at Sultan-Abada are riven into immense chasms.

IN a paper read before the Institution of Mining and Metallurgy on October 16, Messrs. T. H. Leggett and F. H. Hatch collate the facts on which estimates can be based of the gold

production and life of the Main Reef Series, Witwatersrand, down to 6000 feet, and then deduce what, in the circumstances, they consider to be a fair estimate. They conclude that it must be assumed that the annual production will increase for a few years to a maximum, will be maintained for a second period, and that then there will be a third period of decline. For the three years preceding the war, the average increase of production was at the rate of 4,000,000*l*. per annum, the production for 1899 having a value of about 19,000,000*l*. Allowing eighteen months from January 1, 1902, for the industry to be restored to the conditions existing in August, 1899, a similar increase of production will bring the output to at least 30,000,000*l*. per annum by June 30, 1906, and if this rate of production were to be maintained from then on, the total production of 1,233,560,709*l*. would give a life from January 1, 1902, of 42½ years. But as the production will decline gradually instead of coming to a sudden stop, this length of life will be increased, unless the annual output should for any considerable period exceed 30,000,000*l*., when the increase in length of life due to declining output would be neutralised.

MR. C. J. WOODWARD, Municipal Technical School, Birmingham, sends us a photograph, from which the accompanying

illustration has been reproduced, showing Indians in the art of producing fire by means of the fire drill. The photograph is a copy of one in the possession of Mr. Henri d'Este, and was taken in the Orinoco region of South America.

IN a recent number of the *Sitzungsberichte* of the Vienna Academy of Sciences, Dr. J. Hann contributes an important paper on the meteorology of the equator, based on observations taken by Dr. E. Goeldi, director of the museum at Pará. Very few stations exist near the equator, and especially equatorial South America; the observations now in question extend from August, 1895, to August, 1901, and, although they are still continued, Dr. Hann considers them to be of such exceptional value that he has preferred to submit them to an elaborate discussion rather than to wait for later materials. In this note we shall refer only to temperature and rainfall. The results show that the temperature is extremely uniform throughout the year; the annual variation amounts only to 1°·4 C., while the mean daily variation is 8°·8. The lowest temperature occurs in the beginning of the year, and the highest at the end of the year; from May to September the mean temperature is almost constant. The yearly mean is 25°·7 C. The rainfall is characterised by a wet season, January to April, and a relatively dry period, from May to December, although rain is somewhat frequent during the dry season. The falls occur almost exclusively in the afternoon and evening, during thunderstorm weather. The mean annual rainfall is about 102 inches.

A SURVEY of the principal changes that have occurred in the birth and death rates in Italy during the last forty years has been given by Prof. Giuseppe Sormani in the Lombardy *Rendiconti*, xxxv. 16. The principal conclusions are as follows:—The birth rate fluctuated between the limits 39·34 per 1000 in 1876 and 33·49 in 1898, while the corresponding limits of the death rate were 34·39 in 1867 and 21·87 in 1899. The fluctuations are thus seen to be less marked in the birth rate than in the death rate, but both show a downward tendency, which occurs to a great extent concurrently with the introduction of improved sanitary conditions. Still, the birth rate has in every year exceeded the death rate, the excess varying from 2·40 in 1867 to 12·80 in 1897. During the period 1862–1899, the population increased by 10,000,000. In connection with the decreased death rate, the author estimates an annual saving of eight lives per thousand in the period 1897–99 as compared with the period 1862–75. Taking account of the influence of the diminished birth rate, and assuming that the reduction of the death rate is due to progress in checking the spread of infectious diseases, it is considered that at least 200,000 people have been effectively saved from death, and that the number of those saved from illness must be at least twenty times as great.

IN "Notes on the Geology of the Eastern Desert of Egypt," by Mr. T. Barron and Dr. W. F. Hume (Dulau and Co., 1902), there are some interesting remarks on the later physical changes which the country has undergone. Attention is drawn to certain "igneous gravels" which in reality are gravels containing in places fragments of granite, gneiss and other stones derived from the Red Sea hills. They are probably Pleistocene and of earlier date than the Nile, as its bed has been cut through them and its alluvium overlies them, so that this river could not have begun to flow until late Pleistocene times. A study of the raised beaches and coral reefs affords evidence of important movements which ushered in the present conditions. During the Pliocene period, minor fault-valleys were formed, and likewise great rifts such as the Red Sea (with the invasion of the fauna of the southern seas), the Gulf of Suez and other features. Miocene strata afford evidence of the former extension southwards of the Mediterranean; Oligocene strata have not been recognised; while the earlier Eocene strata, preserved here and there from destruction by faults, point to the Eocene sea having covered the entire area examined. These Eocene strata are Londinian in age, but they comprise two series, an upper, mainly composed of limestones with nummulites, and a lower, of shales and marls. The lower series rests unconformably on Upper Cretaceous limestones, which are characterised by abundant oysters and well-marked bone-beds. Certain gypseous deposits near the Red Sea have resulted from the chemical alteration of Cretaceous and Eocene limestones. The Nubian Sandstone, which underlies the Cretaceous limestones, is also regarded as of Cretaceous (Santonian) age, and it rests on smoothed surfaces of Plutonic, volcanic and metamorphic rocks, planed down by marine erosion.

WE have received a copy of a paper by Dr. J. Beard, from the *Zoologischer Jahrbuch*, entitled "The Determination of Sex in Animal Development."

THE *Revue générale des Sciences* of October 15 contains an admirably illustrated account of a discourse on "extinct monsters" recently delivered by M. Marcellin Boule in the

Paris Museum. Among the illustrations, especial interest attaches to a reproduction of a photograph of the skeleton of *Mastodon angustidens* lately acquired by the museum, showing the remarkable downward flexure of the upper tusks and the great length of the symphysis of the lower jaw in which the lower pair are implanted. It seems certain that this species could not have been provided with a long trunk.

AMONG a batch of articles from the *Proceedings* of the U.S. Museum, attention may be directed to one by Major E. A. Mearns on the ocelot cats, of which five distinguishable forms (regarded as species) are recognised. In a second fasciculus (No. 1292), Mr. W. P. Hay describes the crustaceans inhabiting "Nickajack" Cave, Tennessee. In other parts (Nos. 1293 and 1296), Messrs. Jordan, Snyder and Fowler continue their description of Japanese fishes, treating in the former fasciculus of the blennies, and in the latter of the gorgeously coloured chætodonts and their allies.

WHEN discussing the extent to which the posterior vertebral segments of the body have been suppressed and transmuted during the evolution of man and the higher apes, Dr. A. Keith (*Journal of Anatomy and Physiology*, vol. xxx. p. 18) calls attention to the fact that naturalists are wrong in describing the larger apes as quadrupedal. They are so only when on the ground, which is not their proper habitat. When at home among the trees they carry the body upright, and may thus be called *orthograde*, in contradistinction to the lower Primates, which are *pronograde*.

THE third part of the first volume of Mr. J S. Gardiner's "Fauna and Geography of the Maldive and Laccadive Archipelagoes" contains articles by five contributors, in addition to a continuation of the editor's general description of these islands and the coral-reefs of the Indian Ocean generally. In the first article, Prof. F. J. Bell discusses certain groups of echinoderms; in the second, Mr. M. Burr describes the orthopterous insects; while the third, by Mr. L. A. Borradaile, treats of certain crabs. The fishes of the Maldives fall to the lot of Mr. C. T. Regan, and for the identification of the turbellarian worms Mr. F. F. Laidlaw is responsible. A full notice of the work is reserved until its completion.

To the October number of the *Zoologist* Mr. Graham Renshaw contributes an interesting series of notes on various zoological gardens. A plate, from photographs, illustrates the remarkable difference between the summer and winter coats of the addax antelope. Attention is called to the fact that the attitude generally given to the South American maned wolf in museums and figures is incorrect, the creature carrying its head very low.

IN Gegenbaur's *Morphologisches Jahrbuch*, vol. xxx. part iii., Herr L. Tobler points out that the so-called axillary bands (Achselbogen) of the human subject are vestiges of the panniculus carnosus (skin-muscle) of the lower mammals.

THREE reprints from the *Yearbook* of the Department of Agriculture, and *Bulletin* No. 32 from the Bureau of Forestry in the same Department, all dealing with forestry questions, have been received. The work, mainly of supervision or providing expert advice, which is carried on by the Department is here emphasised on three distinct lines. Two of the pamphlets give working plans for forests, the one in Arkansas drawn up by Mr. F. E. Olmsted for a lumber company, and the other arranging for economic lumbering of land belonging to the University of Tennessee, on a system suggested by Mr. J. Foley. In Arkansas, 85 per cent. of the company's holding consists of pine lands, where about 50 per cent. of the trees are pines, of the varieties short-leaf and loblolly (*Pinus echinata*, *Pinus taeda*), but both furnishing timber known as yellow pine. The remaining 50 per cent. are hard woods, commercially less valuable, and it is recommended to increase the pines by leaving trees to furnish seed and to decrease the number of hard-wood trees. The cutting limit recommended for pines is 14 inches on the stump, and for hard-wood 20 inches. Mr. W. L. Hall deals with the "Timber Resources of Nebraska," and points out that not only is the amount of planted timber satisfactory, but that the natural timber is increasing both in area and density. The gain in area represents the encroachment of the forest on the prairie, particularly along the creeks and in the ravines, and may in places amount to as much as 100 acres during a period of fifty years. Pine again forms the staple product, except near water, where oak, elm and walnut thrive. "Grazing in Forest Reserves" is the title of the report by Mr. F. Roth, and this furnishes an account of the existing arrangements under which farmers may graze sheep, cattle or horses on the Government forest reserves. The success of this regulated grazing seems to be due to the simple though fairly stringent rules drawn up, combined with the level-headedness of the average American. All the reports call attention to the great damage wrought by fires, and grazers are compelled by their agreement to aid in extinguishing fires, though Mr. Roth combats the prevalent idea that many fires are to be laid to the charge of the shepherds, because fires are quite as frequent where grazing is not allowed.

AMONG the lectures to be delivered at the Royal Victoria Hall, Waterloo Road, S.E., during the next few weeks are the following:—November 4, Mr. Herbert Rix on "To Palestine and Back"; November 18, Mr. Rudler on "Volcanoes."

MESSRS. SANDERS AND CROWHURST, Shaftesbury Avenue, have sent us five lantern slides reproduced from the remarkable photographs of young cuckoos in nests, mentioned in NATURE of October 9 (p. 574). These and other lantern slides of birds and plants photographed direct from nature provide a pleasant means of creating interest in natural history.

THE first two of the three volumes of "The Elements of Physics," by Profs. Edward L. Nichols and William S. Franklin, have been revised and published as a second edition by the Macmillan Company of New York (London: Messrs. Macmillan and Co., Ltd.). The first volume deals with "Mechanics and Heat" and the second with "Electricity and Magnetism."

THE Zoological Society has just issued a new (fifth) edition of the catalogue of the Society's library in Hanover Square, prepared by Mr. F. H. Waterhouse, the librarian. The volume contains the titles of about 11,000 different works, exclusive of periodicals. The whole library contains about 25,500 different volumes. The Zoological Society is also issuing an index-volume to the *Proceedings* of their scientific meetings for the last decennial period 1891–1900, in correspondence with similar indexes for former decennial periods.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. J. D. Tannahill; a —— Monkey (*Cercopithecus*, sp. inc.) from West Africa, presented by Mr. A. J. Lyttleton Turner; a Spotted Ichneumon (*Herpestes auropunctatus*) from Nepal, presented by Mrs. F. Cameron; a Collie's Squirrel (*Sciurus collioei*) from Mexico, a Ruffed Lemur (*Lemur varius*, var. *ruber*), a Fringed Gecko (*Uroplates fimbriatus*) from Madagascar, a Gould's Monitor (*Varanus gouldi*), three Limbless Lizards (*Pygopus lepidopus*) from Australia, deposited; a Golden Eagle (*Aquila chrysaëtus*) from Scotland, presented by Mr. J. Baxendale.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN NOVEMBER :—

Nov. 2. 13h. 6m. Minimum of Algol (β Persei).
4. 1h. 0m. Mercury at greatest western elongation (18° 50′).
5. 9h. 55m. Minimum of Algol (β Persei).
6. 5h. 0m. Saturn in conjunction with the moon. Saturn 5° 33′ S.
9. Predicted perihelion passage of Swift's comet (1895 II.).
14–15. Epoch of Leonid meteoric shower.
15. Venus. Illuminated portion of disc = 0·998, of Mars = 0·914.
20. 12h. 6m. to 13h. 7m. Moon occults 60 Cancri (mag. 5·7).
20. 18h. 42m. to 19h. 51m. Moon occults κ Cancri (mag. 5·0).
23. Epoch of Andromedid meteoric shower.
23. Perihelion passage of Perrine's comet (1902 *b*).
23. 14h. 14m. to 15h. 0m. Moon occults υ Leonis (mag. 4·5).
24. 2h. 21m. to 6h. 4m. Transit of Jupiter's Sat. III. (Ganymede).
25. 11h. 37m. Minimum of Algol (β Persei).
28. 8h. 26m. Minimum of Algol (β Persei).
28. 14h. 0m. Venus in superior conjunction with the sun.
29. 7h. 43m. to 12h. 37m. Transit of Jupiter's Sat. IV. (Callisto).

THE LEONID SHOWER.—Two articles in *Popular Astronomy*, No. 98, by Prof. Pickering and Mr. R. B. Taber respectively, deal with the reports of different observers of the Leonids during the shower of 1901, which, although not seen in this country, appears to have been a brilliant one as seen by the observers in the United States on the morning of November 15.

Prof. Pickering records the following six observations :—

Station.	Latitude.	Longitude.	No. of meteors per hour.
	°	°	
Trinidad, W.I.	10	63	290
Steamer *Admiral Dewey* ...	26	73	420+
Tuape, Sonora, Mex. ...	30	110	countless
Tucson, Arizona	32	111	225
Claremont, California ...	34	118	800
Mount Lowe Observatory ...	34	118	300

The position of the radiant point seems unchanged. the Harvard report giving it as R.A. = 10h. 6m., Dec. = 22° 16′. Mr. Upton, of Providence, estimated it to be R.A = 10h. 2m. ·8., Dec. = 21° 19′, whilst M. Eginitis, director of the Athens Observatory, suggests "a sensible displacement in right ascension." Mr. Upton thinks that "the radiant is probably a point, rather than a spot 2″ or more in diameter."

OBSERVATIONS OF ζ GEMINORUM.—During the period March 10 to May 23 of this year, forty-two observations of the variable star ζ Geminorum were made, by Argelander's method, at the Princetown University Observatory by Mr. F. P. McDermott, junior.

The observations indicate that there is a secondary maximum about 3·0d. before the principal maximum, and that the object attains a brightness of 3·88m. ; a secondary minimum, when the object has a magnitude of about 3·93, is also indicated 1·6d. before the principal maximum.

THE FIFTH SATELLITE OF JUPITER.—Writing to *Popular Astronomy* (No. 98) on September 9, Prof. Barnard recalls the fact that it is exactly ten years since Jupiter's fifth satellite was discovered.

From the spring of 1899 until the spring of this year, Prof. Barnard was unable to see this object, but several good elongations have been observed this year ; the satellite can, however, only be seen under very good observing conditions and with large instruments.

SEARCH FOR AN INTRA-MERCURIAL PLANET DURING THE TOTAL SOLAR ECLIPSE OF 1901.—In *Bulletin* No. 24 of the Lick Observatory, Prof. Perrine describes the photographic search for the intra-Mercurial planet which, according to Leverrier and others, might be the disturbing influence that causes the considerable motion observed in the line of apsides of the orbit of Mercury.

Reduction of the negatives obtained during the 1901 eclipse has led to a negative result. There is just a possibility that at the time of the eclipse the hypothetical planet may have been in a direct line with the bright corona, and so have escaped notice ; but, as the corona only covered 1/200th of the area photographed, this is not very probable.

A planetary body 34 miles in diameter would have appeared as having a magnitude of 7¾ in the existing circumstances, and, as it would need seven hundred thousand such bodies, each having the same density as Mercury, to produce the observed movement in the orbit of the latter, it seems highly improbable that these changes are due to the interference of an intra-Mercurial planet. Prof. Perrine suggests that perhaps the finely divided matter which produces the zodiacal light may, when considered in the aggregate, be sufficient to cause the perturbations in the orbit of Mercury.

CHEMISTRY AT THE BRITISH ASSOCIATION.

IN a paper on experiments to ascertain the amount of carbonic anhydride absorbed from sea water, Prof. E. A. Letts and Mr. W. Caldwell stated that they are experimentally testing the validity of Schloesing's theory that the ocean serves as the regulator of atmospheric carbonic anhydride, with the aid of a specially devised piece of apparatus. Prof. E. A. Letts also read a paper on the corrosion of copper by sea water and on the detection of traces of impurity in the commercial metal, in which it was suggested that rapid corrosion of copper by sea water may be due to electrolytic action between particles of a copper-arsenic alloy embedded in the copper plates and the copper itself. Prof. F. Clowes, in a paper on the action of distilled water upon lead, showed that dissolved oxygen first acts upon the lead, and the oxidation product is subsequently converted into a hydroxy-carbonate by carbonic acid. Dr. C. E. Fawsitt gave a paper on the decomposition of urea, showing that on heating urea in aqueous acid or alkaline solution at 99°, the decomposition does not proceed in accordance with a bi- or tri-molecular reaction as would be expected theoretically, but in accordance with the formula of a monomolecular reaction. The apparent anomaly is explained by the formation of ammonium cyanate as an intermediate product ; on heating with water, urea first undergoes isomeric transformation into ammonium cyanate, and this then decomposes into ammonia and carbonic anhydride. In a paper on the telluric distribution of the elements in relation to their atomic weights, Mr. W. Ackroyd employs the purchasing power of a given sum as an indication of the abundance or rarity of the different elements ; he shows that in each of the natural groups the rarity of the element increases with the atomic weight. In a paper on the proposed standardisation of methods of chemical analysis, Mr. B. Blount protested against the growing tendency to apply the principle of standardisation to analytical methods for the determination of chemical entities, such, for instance, as the constituents of steel ; at the same time, he agreed that arbitrary methods, such as those applied to the examination of waters, oils, milks, &c., should be standardised. Prof. T. Purdie, F.R.S., and Dr. J. C. Irvine, in a paper on the alkylation of sugars, described a method for alkylating hydroxyl groups in methylglucosides. On boiling methylglucoside in methyl alcohol with methyl iodide and dry silver oxide, the trimethyl ether of methylglucoside,

$$CH(OCH_3).CH(OCH_3).CH(OCH_3).CH.CH(OCH_3).CH_2.OH,$$
$$O$$

is produced ; on further heating with methyl iodide and silver oxide, it is converted into a tetramethyl ether. Under similar treatment, acetonerhamnoside yields a dimethyl ether. In dealing with the synthetical action of enzymes, Dr. E. F. Armstrong showed that the enzyme lactase is capable of converting glucose into a disaccharide, to which the name isolactose was given. The same author gave a paper on recent synthetical researches in the glucoside group ; the pentacetylglucoses are converted into aceto-halogen-glucoses by anhydrous hydrogen chloride or bromide, the acetyl group attached to the aldehyde group being replaced by halogen. These substances are converted into alkylglucosides by treatment with alcohols. A report of the committee appointed to collect

statistics concerning the training of chemists employed in English chemical industries, of which Prof. G. G. Henderson is secretary, was read; information concerning their course of training had been received from 502 managers and chemists employed in English chemical industries, 111 of whom are fellows or associates of the Institute of Chemistry. The following figures give more detailed information:—

Number of graduates of a British University	59
Number of graduates of both a British and a foreign University	16
Number of graduates of a foreign University......	32[1]
	107
Number of non-graduates trained in a British University or University College	137[2]
Number of non-graduates trained in a British Technical College	165
Number of non-graduates trained in a foreign University or Technical College	8
Number of non-graduates trained in Evening Classes, analysts' laboratories, works' laboratories, or otherwise	85
	395

The committee on isomorphous sulphonic derivatives of benzene, of which Prof. H. E. Armstrong, F.R.S., is secretary, reported that Dr. Jee has completed the crystallographic study of the 1:3-dichloro-, chlorobromo- and dibromo-benzene 5-sulphonic chlorides and bromides, and finds that this group of compounds constitutes an isotetramorphous group. In discussing the colour of iodine-containing compounds, Miss Ida Smedley called attention to the fact that two classes of such compounds are known, namely, colourless and coloured. In a paper on colloids of zirconium compared with those of other metals of the fourth group, Dr. J. H. Gladstone, F.R.S., and Mr. W. Hibbert stated that zirconium gives a colloid of well-marked properties resembling those of silicon, tin, titanium and thorium; Dr. J. H. Gladstone also gave a paper on fluorescent and phosphorescent diamonds. The following papers were also read:—Note on a fourth methylmorphimethine, by Mr. J. Hawthorne; on the absorption of ammonia from water by algæ, by Prof. E. A. Letts and Mr. J. S. Totton; on determinations of atmospheric carbonic anhydride made on board the *Discovery* on the voyage to the Cape and thence to New Zealand, by Prof. E. A. Letts; a new method of causing isomerisation, by Prof. R. Meldola; acid esters of methylsuccinic acids, by Prof. J. J. Sudborough and Mr. W. A. Bone; compounds of trinitrobenzenes and alkylated naphthylamines, by Mr. H. Hibbert and Prof. J. J. Sudborough; action of alkalis on cinnamic acid dibromide and its esters, by Prof. J. J. Sudborough and Mr. K. J. Thomson. An interesting feature of the proceedings of Section B was the reading and discussion of two important monographs, one on our present knowledge of diazo-compounds, by Dr. G. T. Morgan, and the other on hydro-aromatic compounds with single nucleus, by Dr. A. W. Crossley.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE papers read before the Section covered, as will be seen, a considerable portion of the field that is usually embraced by anthropology.

Archaeology.—Mr. W. J. Knowles exhibited some Irish flints mostly with a dark brown patina and "the fashion of chipping the flint perpendicularly through the thickness," some of which came from "interglacial gravels." Two questions were asked: (1) What useful object could the perpendicular chipping serve to man? (2) If not artificial, what force in nature can dress so many objects alike with chipping that has all the appearance of being artificial in character? Miss Nina F. Layard described and exhibited a number of variously shaped Palæolithic implements from a small pit in the plateau gravels of Ipswich, and Messrs. W. and W. A. Cunnington gave an account of the recent discovery of Palæolithic implements from Knowle, Wiltshire; these implements and the ordinary flints of the gravel pit are remarkable for the very high polish that many exhibit, and some are marked with peculiar striæ. There are two views to account for the polishing, (1) a redeposit of silica, which was favoured by the authors, and (2) sand action, which was emphatically advocated by Prof. Boyd Dawkins; as a matter of fact, the sand of this quarry is exceptionally fine and entirely siliceous. Mr. S. B. Dixon also exhibited some of these polished implements. No satisfactory explanation was given of the striæ. Mr. W. J. Knowles described some important stone-axe factories that he had discovered near Cushendall, co. Antrim; axes in all stages of manufacture and innumerable chips were found where boulders of a certain rock occurred in the drift. The conditions were somewhat similar to those Mr. W. H. Holmes has described in the United States. Mr. Knowles also exhibited leaf-shaped stone blades from co. Antrim, which were probably a stage in the manufacture of spear- and arrow-heads, like the stone blades from America.

A remarkable series of underground, tunnel-like dwellings (souterrains) in Ulster was shown in lantern slides by Mr. W. J. Fennell, and similar remains from various parts of the British Isles were copiously illustrated by Mr. D. MacRitchie. Mr. G. Clinch also described the subterranean dwellings recently discovered at Waddon, near Croydon.

The report on the excavations at Arbor Low Stone Circle in Derbyshire was read by Mr. H. Balfour. The evidence as to its age was not decisive, but it pointed to the monument having been erected at the close of the Neolithic period, or at the beginning of the Bronze age. A Belfast antiquary endeavoured to prove that the Irish elk survived into the Bronze age, but the bones exhibited belonged to oxen, not to deer.

A note from Mr. R. A. S. Macalister on a prehistoric cemetery-cave in Palestine recorded the first discovery yet made of the pre-Israelite inhabitants of Palestine who burnt their dead; above these were found unburnt remains of the earliest Semitic stock. The recent Cretan excavations at Knossos by Mr. A. Evans and those at Palæokastro by Mr. R. C. Bosanquet were illustrated by lantern slides; at the latter site there is an exceptional opportunity for a craniological study of Mycenæan and recent Cretans.

The Hon. John Abercromby read a very important paper on the oldest Bronze age earthenware vessel, which is usually called a "drinking cup" and for which he proposed the term of "beaker." By the aid of numerous photographs, he demonstrated that it came into Britain from the Rhine and in all probability had its origin in Central Europe. Bronze objects of the Hallstatt culture phase have been recognised in Ireland, but it was not until Mr. G. Coffey drew the attention of the Section to the fact that the abundance of them was realised. This he did in a very convincing manner, drawing his examples mainly from the wonderful collection of the Royal Irish Academy in Dublin. Iron was probably known before the close of the Hallstatt period in Ireland. Mr. Coffey also exhibited lantern slides of some remarkably fine carved Irish monuments belonging to the La Tène, or so-called Late Celtic, period. These stone monuments, which are ornamented with the "trumpet" design, are unique. Reports were read on excavations in the Roman fort at Gellygaer, near Cardiff, and in the Roman city of Silchester. The survival of certain Pagan sepulchral symbols on early Christian monuments in Ireland was abundantly illustrated by lantern slides by Mr. P. J. O'Reilly. The significance of these symbols is, however, unknown. A note was presented by Mr. F. P. Mennell on the Khami ruins twelve miles from Bulawayo, Rhodesia. It is satisfactory to find that these monuments are being investigated and the specimens preserved in the Rhodesia Museum.

Anthropography, or *Physical Anthropology*.—A new departure was made at this meeting in the formation of a subsection to discuss matters relating to this branch, and a demonstration was made by Prof. Symington in the anatomical museum of the College. Mr. J. F. Tocher read his report on the pigmentation survey of Scottish school children. Preparations are now being made for an exhaustive inquiry into the distribution of the hair and eye colour of Scottish children analogous to that made by Virchow for German children. Mr. Tocher also presented a note on some measurements of Eskimo. Mr. J. Gray gave measurements of the Indian Coronation contingent, and drew therefrom some interesting conclusions. Dr. C. S.

[1] Thirteen of whom studied also in a British University or Technical College.
[2] Twenty of whom studied also in a foreign University or Technical College.

Myers presented his report on the very numerous anthropometric investigations he has made among the native troops of the Egyptian army, and at the same time described a method of radial craniometry. The skeleton of Cornelius Magrath, the Irish giant, was exhibited, and the subject of giantism was lucidly explained, by Prof. J. D. Cunningham; Prof. A. F. Dixon also exhibited a skull modified by acromegaly. Prof. J. Symington exhibited some ancient Irish crania collected by the late John Grattan, of Belfast, and described the methods of cranial investigation adopted by that gentleman; the president also alluded in eulogistic terms to the acumen of Mr. Grattan, who, though he was engaged in business and had not received a scientific training, yet was in his time in advance of every European craniologist so far as methods were concerned.

Psychology.—Miss A. Amy Bulley read a paper on the psychology of primitive man; while primitive man had no absolute mental deficiency, he "sensed" objects singly and without anything more than a hazy perception of their relation to one another. The results of this deficiency were:—(1) Inability to generalise; (2) no distinction recognised between essential and non-essential characteristics; (3) imperfect understanding of cause and effect. These imperfections were employed as tests for certain religious ideas that have been attributed to primitive man, such as one supreme God, phallic worship, the ghost theory and the theory of the *continuum* in religion. Dr. W. Graham's paper on the mental and moral characteristics of the people of Ulster led to a very lively debate which was fortunately free from excess, although the author referred to the increase of insanity due to religious excitement in the north of Ireland. The main valid criticism was the pointing out that the author fell into the common mistake of calling the non-Teutonic element in Ireland "Celtic," thereby entirely ignoring the vastly preponderating Mediterranean strain.

Ethnography.—There were several papers, illustrated with lantern slides, which described certain peoples who had been studied by the lecturers. Dr. W. H. Furness gave an entertaining and instructive discourse on the Nagas, whom he visited with the special purpose of investigating whether they had a connection with any of the interior tribes of Borneo; he came to the conclusion that there was no positive proof for this view. The Lolos and other tribes of western China were dealt with by Mr. A. Henry. A comparison of the Lolo and Mias-tze speech with the Chinese suggests that the tonal monosyllabic languages form a distinct primitive group and are not the result of linguistic degradation; the peculiar script of the Lolos may be due to early Nestorian missionaries; the surnames of the Lolos always signify the name of a tree or animal, which may not be touched. Messrs. Nelson Annandale and H. C. Robinson described the wild and civilised tribes of Malay Peninsula. No distinction could be drawn between the Malays and Siamese of the district between Singora and Jambu; there is evidence of an admixture of aboriginal blood; the savage tribes are the Semangs, Sakais and Orang Laut Kappir of Trang. The report on the ethnological survey of Canada was presented. The Canadian Committee itself has not yet got beyond the "resolution" stage; the long report of more than ninety pages is solely the work of the secretary, Mr. C. Hill-Tout, who has investigated, mainly linguistically, the Lower Fraser Indians of British Columbia. The Royal Society of Canada has at last undertaken to prosecute with vigour the important and pressing objects of this committee.

Comparative Religion.—The human souls and ghosts of the Malays of Patani were described by Mr. N. Annandale, as well as the ghosts of inspired magicians, the giving in marriage of the son of such a ghost, and the marriage procession (a cyclone); the evolution was traced of a local god from such a ghost. Two papers by the Rev. J. H. Holmes were read by the president. The first described the sacred initiation ceremonies undergone by the lads of the Papuan Gulf. The boy is isolated in the "eravo," or club house, until his hair has grown to its full length. His body must not be exposed to the sun, and he is subject to several taboos. The bull-roarer is shown and explained, and masks play a great part in the more important ceremonies. The second paper dealt with the religious ideas of the Elema tribe of the Papuan Gulf. From certain customs and taboos, it is evident the natives were totemic people, but they appear to have partially passed beyond this phase. There are four classes of ghosts—those who have died a natural death, who have been killed in a fight, who have been murdered, and who have been killed by a crocodile. Every family of living things, from man downwards, has its special god or guardian spirit, for whom there is a feeling of respect; for example, the banana has two gods. The Toaripi or Elema recognise a good and an evil supreme god and a number of subsidiary ones. Mr. F. T. Elworthy exhibited a number of perforated stone amulets from Lincolnshire, Dorset, Somerset, co. Antrim, and southern Italy which are used as prophylactic agents against witchcraft in houses, cattle byres, or in gardens. An important paper on the Lia Fail of Tara and election of kings by augury was communicated by Mr. E. S. Hartland. The famous Lia Fail, or Stone of Destiny, often, but erroneously, identified with the Coronation Stone, was a stone on which were enchantments, for it used to roar under the person who had the best right to obtain the sovereignty of Ireland at the time the men of Ireland were in assembly at Tara to choose a king over them. It was thus an oracle, and the choice of king was made by the augury which it gave. Kingship was something more than human; it was thus necessary to ascertain the will of the gods. Other examples from diverse times and places were given as proofs of the widespread character of these customs.

Survivals.—Mr. E. Lovett discoursed in an interesting manner on tallies; these are records kept by cutting notches in sticks of wood, and are a survival of probably the earliest appliance of a commercial nature made by man. There are two varieties: (1) the contract tally, formed by a stick split through the notches, and (2) the simple or memorandum tally, a single notched slip of wood. The simple or folk tally has survived the complex form as elaborated in the banker's and exchequer tallies. Numerous modern examples were exhibited. Mr. Hartland exhibited two wooden "swords" formerly worn as professional emblems by medical practitioners in Japan; one represented a bean pod, and the other was a rough piece of wood.

Museums.—On the last morning, a very interesting discussion on the classification and arrangement of exhibits in anthropological museums was started by the reading, by the recorder, of a very suggestive paper by Dr. W. H. Holmes, of the U.S. National Museum. The chief methods of arrangement are the ethnographical on a geographical basis, and the evolutionary and distributionary. It was generally agreed that no hard and fast rule could be laid down, but that it was desirable that every museum should develop along its own lines, subject to a controlling idea along one of these chief directions. It was held essential that museums should be liberally labelled, and rendered at the same time instructive and interesting; more attention should be paid to these points, as the success of a museum depends upon the interest that it awakens.

Classification.—The business of the Section terminated with a discussion of the classification of the subject-matter of anthropology; this was opened by Mr. E. N. Fallaize with a suggested scheme which was offered for future consideration.

A popular feature of the Section was the interesting museum mainly of local archæology and ethnographic survivals which, thanks to the courtesy of Prof. Symington, were exhibited in the dissecting room and anatomical museum. Mr. R. Welch exhibited numerous photographs and other objects, notably a series of remarkable primitive vehicles from co. Antrim, which illustrated several stages in the evolution of the Irish jaunting car. Many of the papers read at the meeting will be published in full by the Anthropological Institute either in their *Journal* or in *Man*.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

PROF. HALLIBURTON, president of the Section, read a paper on the regeneration of nerves, contributed by Dr. Mott and himself. Two opinions existed in regard to the regeneration of nerve-fibres. One set of observers concluded that the new nerve-fibres sprout out from the central stump of the divided nerve-trunk. This was the opinion of by far the larger number of workers. The other opinion was that the new nerve-fibres were of peripheral origin. Those who held the latter view relied almost entirely upon histological evidence. But a strand of cells that looked like a nerve-fibre to the microscope might nevertheless be not physiologically a nerve-fibre, inasmuch as it might be quite unable to be excited as a true nerve-fibre is or to conduct nerve impulses as a nerve-fibre can. These functional performances were the true criteria for nerve-fibres. Among recent

observers, Howell and Huber, who had used both histological and experimental methods, had arrived at the conclusion that the axis cylinder, the essential portion of a nerve-fibre, had an exclusively central origin; they admitted that the peripheral tissues in which it was embedded were active in preparing and generating a nutritive scaffolding for it. With Dr. Mott he had come to experimental results which, so far as they at present went, confirmed those by Howell and Huber. One experiment they had performed was to divide a large nerve and suture the ends together. After a sufficient length of time had passed, restoration of function occurred, and this was taken as a sign that regeneration had successfully ensued. Then they exposed the nerve-trunk anew. The union of the two ends was then found to have been accomplished, and on testing the nerve it was found to be excitable by faradisation when the stimulus was applied either below or above the point of reunion of the divided trunk. A piece of the nerve-trunk was then excised some little distance below the point of reunion; on microscopical examination of this, new nerve-fibres were discovered within it. Subsequent to this second operation, the wound was closed up and the animal was finally sacrificed ten days later. When the animal was finally then examined, the nerve both above and below the second section was once more tested for response to electric stimulation. The peripheral piece was then found to have become once more inexcitable. Degeneration had also set in within the fibres of the peripheral piece of the nerve-trunk. Prof. Halliburton urged that this showed that the degenerative process which followed the direction of growth had occurred in a peripheral direction only and had not started at the periphery. Observations were also mentioned indicating that normal functional activity exercised an important influence on the speed and perfection of the process of nerve repair. Paralysis was induced in the arm of the monkey by section of a number of the cervico-brachial afferent spinal roots. By this device, the motor cells of the cord in that region, namely, the cells whence originate the motor nerve-fibres of the limb, are cut off from the influence of all impulses coming to them reflexly from the sensory nerves of the limb itself. A large nerve-trunk in the arm is then divided and the corresponding nerve-trunk of the opposite non-paralysed limb is likewise cut, the latter as a control experiment. Union of the ends of the divided nerves occurred on both sides, but on the side on which the afferent roots had been cut the union was much slower and less perfect, as shown both by histological and by electrical examination of the nerve.

Prof. Schäfer communicated the results of a series of experiments executed with the object of analysing further the mechanism connecting the muscular apparatus with the centres for willed movement having their seat within the brain. He compared the relative effects of transection of the pyramidal tracts and of the ventral columns of the spinal cord. The observations had been made on monkeys. Section of the ventral columns of the spinal cord produced paralysis of voluntary movement in the parts of the body lying behind the segmental level of the lesion. The descending fibres of the ventral columns of the cord were in the main derived from the cells of the nucleus of Deiters in the bulb, a group of fibres that were, on the other hand, related to the impulses entering the brain from the labyrinth organ, namely, the semicircular canals and the otolith organ. It had been proved by Ewald and others that the destruction of the labyrinth organ entailed diminution and impairment of the "tonus" of the voluntary muscles of the body. Prof. Schäfer proposed to account for the paralysis ensuent upon transection of the ventral spinal columns by the removal of the bracing influence of Deiter's nucleus from the ventral horn cells of the spinal cord, the tonus of muscles being certainly primarily a tonus of the ventral horn cells of the cord. The paralysis produced by section of the ventral columns of the cord would on this explanation be comparable with that described by Sherrington and Mott in the monkey consequent on section of the afferent roots, which seems to take effect by producing loss of tonus in the motor nerve-cells.

A paper on some new features in the intimate structure of the human cerebral cortex was read by Dr. John Turner. His specimens showed (1) a beaded network enveloping the pyramidal cells of the cortex and their dendrites; (2) an intercellular plexus of nerve-fibrils not previously demonstrated to exist. The preparations demonstrating these points had been made by placing pieces of the brain tissue directly on removal from the body, and without previous hardening or fixing, into a staining solution containing methylene blue and hydrogen peroxide. From this mixture, after a sufficient time had elapsed, the tissue was transferred to a solution of molybdate of ammonia. The tissue was then after this fixation dehydrated, embedded in paraffin and cut into sections. The beaded network is a network, not of neuroglial fibres, but of processes of true nerve-cells. This network loosely invests the pyramidal cells and their dendrites. The network is made up of the finer ramifications of stouter fibres which can be traced from certain pyriform dark cells in the cerebral cortex; these cells are generally small, and no signs of any network can be seen around them. There seem, in fact, in the cortex of the cerebrum to be at least two systems of nerve-cells present, the pyramidal variety, which are pale under the method of examination here employed, and the smaller darkly stained pyriform nerve-cells. These latter possess branches which ramify and form by a fusion a network enveloping the pyramidal cells. Since the network is a true network formed by actual anastomosis, the system of dark cells constitutes a *continuum*. Dr. Turner urged that in all probability collaterals arising from the axons of the pyramidal cells also joined on to the network. If that were so, all the nerve-cells of the cortex would be practically in organic continuity. He suggested that the differences observed in staining, shape, arrangement, &c., of the two varieties of cells indicated a difference in function. There was good ground for associating the pyramidal cells with motor functions; he was therefore inclined to ascribe to the dark pyriform cells sensory functions. They were in all likelihood, he urged, the bearers and distributors of afferent impulses. This method might therefore afford a means of showing where ingoing currents ended and where outgoing currents started. On this view, however, the impulses must flow in a centrifugal direction in the dendrites of the dark cells and in a centripetal direction in the axons of those cells; this was against the views generally in acceptance which regard the axon as always a cellulifugal conductor and the dendrites as always conducting in a direction toward the perikaryon.

Prof. Schäfer corroborated the description of the microscopical structures described and discovered by Dr. Turner. He suggested, however, that the course of conduction was not cellulifugal in the dendrites of the dark cells. He argued that it was more probable that the nervous pericellular network took up impulses brought by the afferent fibres coming to the cortex in such large numbers from the optic thalamus; that these impulses in part were carried through the pyramid cells and in part through the dendrites of the dark cells to the perikarya and axons of these latter.

Dr. Page May communicated a paper upon the movements and innervation of the stomach. His investigation had been an experimental one, and the animals employed had been cats, dogs and monkeys. A short time after taking food, movements of a rhythmic character arise in the muscle of the wall of the organ. These movements are waves of contraction, each of which commences near the œsophageal end of the stomach. The waves succeed each other at a rate of about three times per minute, and they slowly increase in strength as they pass toward the pylories. The contractions have their origin in the wall of the organ itself, because they will continue for half an hour or more after removal of the viscus from the body and its preservation in a bath of warm saline solution. The small ganglia in the wall of the stomach probably coordinate the contractions. Although the gastric contractions are of autocthonous origin, they are subject to control of the central nervous system by means of the vagus nerve, especially of the left vagus nerve. On stimulating the peripheral end of the vagus nerve, the tone of the gastric muscle is usually at once much diminished. Any gastric contractions are usually then abolished. Shortly after this, on the contrary, renewed movements set in, often very vigorous in character, and usually about four times as powerful as the contractions during ordinary digestive activity. Thus the first effect of stimulation of the vagus is inhibition of the gastric tone, the second is increase of tone and augmentation of movement. Stimulation of the central end of the vagus produces a slight inhibitory effect upon the stomach if the other vagus nerve is intact. The splanchnic nerve was not found to exert any influence upon the musculature of the stomach, either in the direction of augmentation or of inhibition. Occasionally some inhibition of gastric movement is excited by the stimulation of the splanchnic, but this not usually; such occasional results are due probably to the vaso-constriction produced by the splanchnic

stimulation. Anæmia of the stomach experimentally produced by blocking the thoracic aorta cuts short the normal contractions of the organ. The cerebral centres for the gastric movements and tone, which have been described by many observers, notably by Bechterew and Opendowsky, were not found, although diligently searched for. No definite result upon the movements of the stomach seemed to result from any cerebral stimulation.

Prof. Schäfer contributed a communication on the diuretic action of pituitary extracts, based on recent researches by Dr. Magnus, of Heidelberg, and himself. He showed a series of tracings exhibiting by the graphic method the effect that intravenous injection of extract of pituitary body has upon the activity of the kidneys. The epithelial part of the pituitary body yields an extract which causes a marked increase in urinary secretion. This part of the gland had always previously been supposed inert. The diuretic action now proven to be exerted by the gland had, Prof. Schäfer urged, a direct bearing upon the disease called acromegaly, in which the pituitary body was enlarged and diuresis was present.

Prof. Gotch brought forward an experiment upon fatigue and nerve. It had long been held that repeated or excessive activity caused fatigue of nerve-endings, but had no effect upon the fibres which conduct the nervous impulses. Herzen had recently questioned the truth of the above generally adopted view. Herzen stated that after a nerve-trunk had been subjected to repeated stimuli, the subsequent response of the nerve shows signs of impairment when examined by electrical tests. This impairment it had been the object of the present observations to examine, and they showed that the impairment was a change which was confined in its situation to the neighbourhood of the place of the electrodes by which the electric currents used for fatiguing the nerve were applied to the nerve. Were the effect a true fatigue effect, its locus should not be confined to the electrode region, but should be distributed throughout the nerve, because the process of conduction of nerve-impulses occupying the whole length of the nerve, the true fatigue which arose as their after effect must have a similar distribution. The changes which were confined to the immediate neighbourhood of the electrodes by which the long series of "fatigue"-producing currents were introduced were those to which much attention has long been devoted as electrotome. Probably the process involved was one of electrolysis, and certainly its relation to fatigue in the true sense was at most extremely remote. For the experiments the capillary electrometer had been employed; the electric differences studied had been given by the nervous impulse in response to a single induction current.

Dr. Edridge-Green brought forward evidence regarding the distribution in the retina of the photo-sensitive pigment, the visual purple. This pigment belongs to the "rods" only, and is not present in the "cones." Nevertheless, Dr. Edridge-Green finds that it is present in the central region of the retina, a region in which there are cones only and no rods. On examining the retina of the monkey, when that animal had, in order to increase the amount of visual purple, been kept in the dark for twenty-four hours, the central region of vision, the yellow spot, instead of being free from visual purple was the most purple part of the whole retina. The purple was, however, seen by microscopic examination to be around and not actually in the cones. He advanced the theory that the cones were only sensitive to changes in the visual purple, not to light itself.

Dr. Osborne communicated the results of researches on glycogen carried out in conjunction with Dr. Zobel. Glycogen when hydrolysed by a diastatic ferment gives rise to bodies very similar to those derived from starch. Amongst these is the so-called isomaltose, shown by Brown and Morris to be a mixture of maltose and a dextrin-like body. When acted on by saliva, glycogen gives dextrins, dextrose and maltose.

Dr. C. S. Myers referred to observations on the smallest perceptible musical tone-difference as examined in the people of Scotland and of the Torres Straits. The investigations had been conducted by means of tuning-forks. The least perceptible tone-difference among the children of Murray Island was not widely different from those of the children of Aberdeenshire. But with practice the Aberdeenshire children improved more readily and uniformly. The adult Murray Islanders for the most part failed to detect a semi-tone interval. The average difference of vibration-frequency just distinguishable by the Adult Murray Islanders was fifteen vibrations per second, whereas for the adult Scotch examined it was nine vibrations.

Dr. Page May gave an excellent demonstration of sections of the brain and of the spinal cord of the camel.

Mr. Barcroft described work dealing with a series of observations on the quantitative estimation of urea.

MAGNETIC WORK OF THE UNITED STATES COAST AND GEODETIC SURVEY, OUTLINED FOR JULY 1, 1902—*JUNE* 30, 1903.

(*a*) *LAND Magnetic Survey Work.*—The determination of the three magnetic elements at 400–500 stations distributed principally in Virginia, New Jersey, Pennsylvania, Ohio, Michigan, Kansas, Nebraska, Texas, Arkansas and Florida.

(*b*) *Magnetic Observatory Work.*—The continuous operation of the four magnetic observatories situated at Cheltenham, Maryland; Baldwin, Kansas; Sitka, Alaska; and near Honolulu, Hawaiian Islands; also the selection of sites and preparations of plans of an observatory in Porto Rico or vicinity, and another in the extreme western part of the United States. [The International Committee on Terrestrial Magnetism and Atmospheric Electricity at the Bristol Conference in 1897 recommended Porto Rico as a suitable and favourable site. The recent magnetic disturbances experienced simultaneously with volcanic eruptions in Martinique will now make the vicinity of Porto Rico an especially important location for a fully equipped magnetic observatory.]

(*c*) *Ocean Magnetic Survey Work.*—The inauguration of magnetic work on board ship in connection with regular trips of vessels engaged in coast survey work. [In this connection it is also proposed during the coming winter to make some trial investigations of the distribution of the magnetic elements over the frozen portions of Lakes Michigan, Superior and Huron in the vicinity of the Straits of Mackinac. The necessary observations at shore stations and on islands will be made in the fall and spring.]

(*d*) *Special investigations* conducted at the magnetic observatories and at certain educational institutions by persons available as "associate magnetic observers."

(*e*) *At the office at Washington* a special effort will be made to bring all computations of field work performed and investigations conducted since July 1, 1899, up to date and prepare results for publication.

THE "SUDD" OF THE WHITE NILE.

A RECENT number of the *Geographical Journal* contains a paper on the "sudd" of the White Nile, by Dr. Edward S. Crispin, explaining the method of opening up the true river bed employed by Major Matthews, who commanded the Sudd Expedition of 1901–1902. The first difficulty is to find the position of the river bed; this is done by probing, the depth suddenly increasing to 15 or 20 feet. Next the top growth, consisting mostly of papyrus, is cut down or burnt; and it was noted that when the papyrus was fired the fire frequently spread along what was afterwards found to be the true bed of the river. Men are then landed on the cleared surface and the sudd cut along the river banks with saws; next transverse cuts are made, dividing the sudd into blocks of size convenient for the steamer to tear out. The bows of the steamer are run into the block, and the loop of a steel hawser, both ends of which are made fast to the steamer, is passed over the bows and trodden into a trench cut on the surface of the block. The steamer then goes full speed astern, men standing on the hawser to keep it in position, and after a number of trials the block is torn away. The block is then towed clear and cast adrift to float down stream, when it is gradually disintegrated. We reproduce figures illustrating (*a*) the steamer towing out a block of sudd, showing the men standing round and holding the hawser in position, and (*b*) the block let go in open water and floating down stream.

The chief growths in the sudd are papyrus and tiger or elephant grass, a kind of bamboo growing to a height of 20 feet or more. Up these climbs a creeper of the convolvulus species. There is also abundance of ambatch and a long

sword-grass that cuts like a knife, known as "oom soof." The steamer could cut its own way through the latter in the presence

FIG. 1.—Steamer towing out a block of sudd.

of a current, as it would break up and float down stream. In the absence of current it does not float away, and obstructs the

FIG. 2.—Block of sudd let go in open water.

steamer by fouling the paddle-wheel. Another source of obstruction is a very light kind of duckweed which covers some of the small open pools.

THE TREATMENT OF SMOKE: A SANITARY PARALLEL.[1]

Introductory.

IN accepting the suggestion that I should take as my subject some aspect of the fog question, I have allowed the importance of the question to override the many considerations which I could adduce in opposition thereto. I propose to consider what demands sanitary reformers may fairly make upon practical men of science and others in regard to the mitigation of the evil effects of fog in towns, and incidentally to point out what demands in this connection, desirable in themselves, must be regarded as beyond the scope even of scientific ambition.

For the sake of clearness, what I have to say is cast in the form of a parallel or analogy. The smoke in fog is the element of the problem to which special attention is directed, and the smoke is regarded as a species of domestic or industrial refuse which has to be removed somehow or other. The removal of smoke is a problem not dissimilar in its fundamental character from that of the removal of sewage, and in what I have to say I keep in view the analogy that exists between the elements of these two problems. I choose the problem of the removal of sewage for this purpose, because it is a problem in which sanitary reformers have achieved gradual but conspicuous success during the nineteenth century, and even within the memory of the present generation, to the great advantage of the whole community.

In all matters concerning the disposal of refuse, we progress by slow degrees from an individualist to a socialist point of view. Occasional illustrations of reckless indulgence of the extreme individualist view as regards the disposal of other forms of refuse might be quoted, and at this day it is no great exaggeration to say that we all act with similar recklessness with regard to our smoke; we throw it into the atmosphere and leave to beneficent chance the question whether or not it injures our neighbours.

In large towns, we have travelled very far in the path of development from the original instinct as regards the problem of the disposal of sewage-polluted water, but there has been no corresponding progress in the disposal of smoke-polluted air. In London, at a cost to the community of 211,000*l.* a year, or 1·38*d.* in the pound on rateable value, nearly a million tons of sewage are removed day by day for about 600,000 houses—about a ton and a half on the average for each house. In the same period, viz. each day, in winter, each house throws into the atmosphere on the average perhaps ten tons of smoke-laden air, or a total quantity of five million tons of smoke-laden air for the inhabited houses of London per day, or possibly seven millions of tons per day if we include factories. The actual weight of solid soot which gives colour and body to the smoke is a very uncertain quantity; it may in the worst cases amount to nearly 3 per cent. of the coal consumed, and the houses of London probably get rid of 300 tons of solid refuse every day by throwing it up the chimney. It is mixed with much larger quantities of other more or less injurious products of the combustion of coal, complete or incomplete, but it is with the soot, which alone darkens and defiles, that I am primarily concerned.

The Initial Stages of the two Problems.

The difference of our attitude towards these two problems is very conspicuous, yet physically speaking the whole difference between the problem of the removal of sewage and that of the removal of smoke on similar lines lies in the distinction that sewage naturally goes downwards, whereas, in the first instance, smoke goes upwards. If the smoke of our fires had been in the habit of falling downwards and finding a lower level instead of rising to a higher level and making its way up the chimney, we should

[1] Abstract of a lecture to the Sanitary Congress at Manchester by Dr. W. N. Shaw, F.R.S.

long ago have been driven into solving the problem of its disposal, as we have been driven to deal with the disposal of sewage, no matter how great the volume might be.

In days not so very remote, the arrangements for the disposal of smoke might be regarded as comparatively in advance. The genius who first put in practice the idea of confining smoke to a narrow flue specially built for it wrought a revolution in house-building. There are still archæological survivals which show that before his day there were architects who were satisfied with the more simple provision of a hole in the roof, and there are even traces extant of a still earlier architectural style of inhabited dwelling in which such rudimentary provision as a special opening for smoke did not exist. I do not attempt to describe the corresponding stages in the development of the means of disposal of other kinds of refuse; they could be traced—*gardy loo* is the survival of a warning with special meaning in the Scottish capital—and examples of present-day practice might be adduced in illustration. But while the disposal of sewage has been generally though slowly progressive since the first commissioners of sewers were appointed in 1531, the invention of the chimney seems to have been so successful as to paralyse mechanical enterprise in that department until the subject was taken up in later years by cowl makers, who have devoted much ingenuity to the improvement of the terminal outlet. For domestic purposes, the simple chimney, with or without the assistance of a cowl, remains a sufficiently effective apparatus; the practice of using it to throw smoke into the atmosphere to be carried away by any currents of air that may arise is universal.

Demands beyond the range of Scientific Ambition.

One of the incidental obstacles to a scientific treatment of the smoke question is that at first sight the atmospheric currents appear to perform the duties of general scavenger with such exemplary efficiency that few people give any thought to the general success or failure of the method itself. On foggy days we become aware of the nuisance which we have created, and accordingly desire that steps should forthwith be taken to remove or prevent fogs, with the understanding that whatever does away with the fog will, at the same time, do away with the smoke nuisance. Now the prevention of fog as a meteorological phenomenon is one of the demands which I think we are not legitimately entitled to ask of practical men of science; it is beyond the ambition even of physical science. To use the parallel further, it would be just as reasonable for us to throw all our refuse into the streets and, when we found that it accumulated beyond endurance, demand of men of science that they should provide showers at suitable intervals to wash it all away. The well-known meteorological conditions for the formation of inland fog are my justification for this opinion.

Nor can we hope for the removal of fog by the actual removal of the foggy air of London. I have on several occasions seen suggestions which seemed to regard such a scheme as possible, but I have never been able to understand where the air would be sent to and by what it would be replaced. Any such proposal has always seemed to me to come perilously near to a scheme for sweeping away the Atlantic with a mop. The removal of foggy air from the streets is as hopeless a matter as the prevention of fog, and when once smoke has been allowed to be discharged into the free atmosphere, all chance of removing it is gone.

Gravity of the Smoke Nuisance.

It is not only on foggy days that the method of leaving the atmospheric currents to act as the smoke scavengers fails. In large towns, the system is generally speaking inefficient. In support of this assertion, I quote from the figures giving the average amount of sunshine recorded at a large number of stations in the British Isles during the twenty years from 1881 to 1900, a comparison between the records for London and the average of those for other places in the southern district of England. The amounts given as percentages of the possible duration of sunshine for the several months are as follows:—

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	
London ...	10	15	23	31	38	36	38	39	34	24	14	9	per cent. of possible duration.
Average for the southern district of England ...	21	28	38	42	46	43	46	47	44	37	24	21	do.
London loss in approximate figures	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{1}{6}$	$\frac{1}{4}$	$\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{2}$	

It appears that in summer London loses one-sixth of its sunshine, and presumably also about the same fraction of its daylight, on account of its smoke, while in winter its loss amounts to one-half for a similar reason.

The contrast of the figures for summer and winter is remarkable. As regards smoke, the difference rests chiefly on the fact that there are fewer domestic fires in summer, and we may therefore legitimately conclude that the domestic smoke is the most serious item to be reckoned with in considering the smoke question. It is, in fact, two-thirds of the problem.[1] Anyone who wishes to satisfy himself as to this aspect of the question can easily do so. During the past winter, Captain Carpenter, R.N., D.S.O., who has been conducting an inquiry for the Meteorological Council into the prevalence and distribution of fogs in London, found that the Victoria Tower at Westminster and St. Paul's Cathedral—two buildings a mile and a half apart as the crow flies—are invisible the one from the other until March is well established. There is here no question of persistent fog in the meteorological sense; even on windy days, when fog is meteorologically impossible, there is no possibility of seeing a distant object in London on account of the domestic smoke from the thousands of chimneys, each using the primitive plan of pouring its refuse into the atmosphere. Not only is the magnitude of the task too great, but the manner in which the atmosphere deals with it is not by any means satisfactory. It does not consume or annihilate the smoke, or render it harmless; it carries its load a little way, longer or shorter according to the state of the weather, and then drops it regardless of consequences. The results are easily recognised. Sooty rains are not by any means an unusual phenomenon, and that is not all. A special type of heavy, dull, oppressive atmospheric condition may generally be noticed on the lee side of all great smoke centres.

That we endure the presence of all this burden of refuse in the air which we breathe, and which carries all our daylight, while we have eliminated the corresponding refuse from our streets and our drinking-water, is partly to be accounted for by the fact that ideas about the treatment of smoke are still in an almost primitive stage; partly also because the inefficiency of the atmospheric currents for renewing the air of our great cities in ordinary weather is not fully realised. It is only during persistent fog that the failure is complete and unmistakable. On foggy days when we thrust our refuse into the atmosphere, it simply descends upon our heads and into our houses. We might almost as well have no chimneys at all. The experience of Sir W. Thiselton-Dyer at Kew could easily be shown to be the experience of all of us who live in large towns if we were able to make such measurements as he made in 1891, when after a week of fog he found upon the greenhouses at Kew—a comparatively favoured atmospheric position for London—a deposit of tarry matter at the rate of six tons to the square mile.

So far as I know, the only practical suggestion put forward by those interested in the abatement of the smoke nuisance is to invite householders and compel factory owners not to make smoke, or to consume it if they make it, or, in the third event, to make as little as may be, consistently with their own interests. As regards factories, very considerable improvement has followed these efforts, and I do not wish to be adversely critical when I point out, first, that the distinction drawn between the factory and the domestic establishment is unscientific if the smoke nuisance is to be really removed, and secondly, that that was not the plan adopted in the parallel case of the removal of sewage, for which the local authorities have used common funds.

Further Development of the Analogy.

In following the analogy somewhat further, I suppose it agreed that the proper course to be pursued is, not merely to

[1] The corresponding figures for Glasgow as compared with Douglas (Isle of Man), the only other station in the same meteorological district, indicate that domestic smoke is only responsible for one-half of the smoke problem in the Glasgow district, though the want of stations makes the comparison incomplete. The figures are as follows:—

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	
Glasgow sunshine	10	17	24	30	33	31	28	28	26	22	11	8	per cent. of possible duration.
Douglas sunshine	21	26	37	43	46	43	39	38	38	32	24	18	do.
Glasgow, loss in approximate figures ...	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{2}$	

prevent smoke by penal legislation, but to encourage the interception of smoke and the removal of the sooty particles before the air is allowed to escape, and I will subsequently call attention to the share which a local authority could fairly take in such an enterprise. I do not say that this is the only or the best mode of dealing with the question; I only consider whether it is, *prima facie*, practicable enough to justify our including inquiries with regard to it in the demands that sanitation may reasonably make upon science. I offer a few considerations in mitigation of criticism of this venturesome proceeding.

First, I am only practically recalling a suggestion made many years ago. A proposal for the treatment of smoke by the erection of municipal chimneys was made in Manchester by Mr. Peter Spence (*Proceedings* Manchester Lit. and Phil. Soc., 1857). It is precisely in such a city as Manchester—a city of fogs and smoke, but also the city of Dalton and of Joule—where the facilities for the association of scientific experiments with real practical life have been so wonderfully developed that an enterprise of this character could be taken in hand.

Secondly, the present method of dealing with smoke is by no means final, although, as I have said, it has marked a most important stage of progress. One of the most conspicuous features of London architecture is the enormous variety of smoke cowls, in all stages of dilapidation, to be seen surmounting the roofs. Almost every chimney stack is a sort of museum of contrivances for improving the action of chimneys. The mere exhibition of so many contrivances can only mean that smoky chimneys are not by any means so rare as they might be under more favourable mechanical conditions. On that very account, if on no other, the separate chimney method of dealing with smoke is not suited to the circumstances of large towns.

Thirdly, the designer of a factory takes a further step in advance in the treatment of smoke, and provides a single smoke stack for a considerable number of independent fires. The separate opening of each chimney of the domestic house into free air is, therefore, not absolutely required for the removal of smoke. The factory builder is not always successful in using his chimney for preventing smoke, but he is successful in leading the foul air of many flues into one channel which might afford an opportunity for depriving the smoke of its soot.

Moreover, arrangements for propelling air mechanically are becoming every day more extended. Some of them as employed in various systems of ventilation are quite as elaborate as any that would be required to deal with the smoke of an ordinary house or block of houses. There is no sufficient distinction to be drawn between coal smoke and other forms of refuse that foul the air to make it necessary to use one system for the former and a different one for the others. It thus seems almost certain that if the domestic architect had sufficient encouragement to make the attempt, he would not find the plan of dealing with household smoke by the method of the factory chimney or by mechanical propulsion beyond the range of practical physics.

Some Particulars of the Smoke Problem.

For purposes of comparison, I next consider what is the amount of smoke-laden air with which we have to deal. It is difficult to give any but the roughest estimate. I assume that on the average every house of the 600,000 rated for the municipal purposes of London has two fires burning, and therefore two chimneys emitting smoky air, for twelve hours each day, and that each chimney uses and defiles 10,000 cubic feet of air per hour. If these estimates are inaccurate, we can at least ask scientific men to correct them. On these assumptions, every "working chimney" delivers 4·2 tons of smoky air per day; every house, on the average, 8·4 tons. We thus obtain the estimate of five millions of tons of smoky air sent up the household chimneys of London in one day. Allowing for the 14,500 factories of London, which are not altogether innocent in the matter of smoke, as equivalent each to thirty house chimneys, we get an additional two million tons of air fouled with smoke; that is, in the aggregate about seven million tons of air are used per day in London to carry away smoke[1] as compared with about a million tons of water to carry away sewage. The cost of dealing with the sewage is about 600*l.* per day. Supposing that a ton of dirty air could be "treated" for the same cost as a ton of sewage, the cost of clearing the air of London might be set down at 4200*l.* a day, equivalent to to a rate of 10*d.* in the pound.

To move air is a comparatively cheap matter. An electrically-driven fan will do the day's work of a single chimney, as regards smoky air, at a cost of about a penny, under suitable conditions. A single colliery fan has been made to deliver as much as 200,000 cubic feet of air per minute, and its output therefore amounts to about 10,000 tons a day, or sufficient to carry the smoke of more than 1000 London houses on the scale mentioned above. Five hundred of such fans would carry the household smoke of the whole of London. It would mean a huge aggregation of power, but London means the same.

These figures show that although the volume of smoky air is vastly larger than the volume of sewage, yet the cost of dealing with it for the purpose of treatment may not be of an altogether different order of magnitude from the cost of the manipulation of London sewage, and the point at which I wish to arrive is, that we are justified in asking practical men of science, as a first question, whether the treatment of smoky air, on a plan somewhat similar to the treatment of sewage, is mechanically possible within reasonable limits of original outlay and current expense.

Limitation of the Analogy.

Beyond this point it would be necessary to diverge in the treatment of smoke from the plan adopted with sewage, both as regards the special method of dealing with it and as to the part which the local authorities should take in encouraging and assisting the purification of air.

I do not suppose that it is possible to establish a few main drains for smoky air corresponding to the main sewage drains, and to use one or two cleansing stations for purifying the air from smoke; but it might be possible to achieve a similar result by a large number of systems on a correspondingly small scale, and the systems might be some of them municipal and some private. A single block of houses might have means for drawing off the smoke from all its fires into a chamber wherein the smoke could be treated,[1] before the fouled air was allowed to pass into the atmosphere, and if such a system were mechanically feasible we should then be able to put a second question to practical men of science, viz., whether it is not possible completely to deposit from the air as it passes on its way the solid particles which form the smoke. It has been shown that sooty particles coagulate under mechanical action, and some years ago Sir Oliver Lodge showed experiments on the deposition of smoke in a closed chamber by means of electricity. I should now like to ask whether it is not possible to make a further advance in this direction. I do not demand that no smoke shall be produced. I think that people may prefer to pay the cost of abstracting the smoke if they enjoy the free use of open fires, to which, in England, we are so much attached.

The Question of Cost.

If men of science give us satisfactory answers as to the physical possibilities, the question then becomes one of cost. Suppose that the cost amounts to the equivalent of a tenpenny rate. Would ratepayers be willing to expend a sum of that magnitude for the purpose of eliminating smoke from the atmosphere of London or Manchester?

In considering this aspect of the question, it should be remembered that the result, if successful, would have some economies to set down per contra.

A bad fog in London, according to the *Times*, may cost 5000*l.* a day for additional gas alone; to that we have to add the loss due to interference with traffic and other incidental items. I have seen the cost of a day's fog estimated variously at from 20,000*l.* to 50,000*l.*, and the cost per annum is set, I think by Mr. Rollo Russell, at from three to five million pounds. If any of these estimates be true, the equivalent of a tenpenny rate would obviously be a very cheap substitute for the smoke of London. Certainly, whatever may be the material damage of a day's fog, the moral and intellectual damage should be reckoned as no inconsiderable addition, and if the indirect results of the dirt of London smoke could be avoided, even an additional tenpenny rate might be found acceptable to a majority of ratepayers.

[1] A layer of air 60 feet thick over the 75,000 acres comprised within the administrative county of London would weigh about 7,000,000 tons. The calculation suggests that on a day of dense fog, when there is very little horizontal movement of air, there is a more or less complete circulation of the air through the chimneys and back again to the streets and houses during the hours when chimneys are active. Dr. W. J. Russell's analyses of air during fog lend support to this suggestion.

[1] The plan of using a single chimney for a building comprising a chemical laboratory and suite of offices—sixteen rooms—has been carried out at the Manchester Alum Works in pursuance of Mr. P. Spence's idea.

Incidental Advantages.

A system such as that indicated would have some incidental advantages. It would provide a persistent and calculable system of ventilation that would enable hot water or steam pipes to be used advantageously much more generally than they can be at present, and afford other facilities corresponding to those of an efficient system of drainage with a copious water supply.

Contribution of Local Authorities to the Solution of the Problem.

Hitherto the powers of local authorities have been restricted to fining conspicuous offenders, and the system of penalties for conspicuous failure is not fully effective; it might be replaced advantageously by a system of rewards for success. For the sake of definiteness, I have set down the contribution of the local authority as equivalent to a tenpenny rate, though it would not seem practicable for it to contribute in the same way as it does to the solution of the sewage question by maintaining a single municipal system. It might contribute effectively by allowing a specific *reduction of rate* on those properties within its area which were so arranged as not to add to the pollution of the atmosphere by smoke.

If the questions which I have mentioned are to be asked, it is essential that they should be put in such a manner that practical men of science may be encouraged to work out effective answers, and for that purpose they must make experiments. In the practical applications of science on the large scale, experiments are very expensive, and the only way of getting them performed is to take care that they are remunerative to somebody if successful. In this matter the local authorities could be of great assistance if they were willing to adjust their rating in what seems to me a reasonable manner. At present the incidence of rating is such as to discourage all experiments of this kind. If an enterprising architect were to erect a block of buildings and provide it with means of delivering its used air free of smoke at a substantial outlay, I presume the local authority would increase the rateable value of the property on account of the outlay, and thus fine the owner some considerable sum per annum for his enterprise. The owner would also be placed in the unfortunate position that whereas by avoiding smoke he had conferred as much benefit upon all his neighbours as upon himself, he would have to pay the whole fine of increased ratal himself, and would still have all the disadvantages of his neighbours' smoke.

I would suggest that instead of pursuing so unreasonable a course, the local authorities might recognise public spirit of this kind by reducing the assessment of a property that, to the satisfaction of its neighbours as well as of a surveyor or inspector, produced no smoke, so that the rates upon such a property should be decreased by, say, 6*d*. or 1*s*. in the pound instead of being increased. This would afford direct encouragement to practical men of science to design and keep in action means for the prevention of smoke, and would lead to gradual improvement.

It would naturally appeal with the greatest force in those quarters where rateable value is high and the advantage of open fires relatively small, and in such places it would be really worth while for practical men to make a serious effort to qualify for the reduction of rate. In the City of London, for example, there must be many properties with very high rateable value the facilities of which for contributing smoky air are already limited to one hot-water furnace and a few open fires. For such establishments it would be an experiment on a very small scale to arrange matters to obviate smoke altogether and satisfy the surveyor or inspector that the property was smokeless, and thus secure the reduction of rate. There might be some difficulty at first in establishing a qualification, but it could not be greater than the difficulty of establishing a right to a parliamentary vote. In the course of time, the smoke producers would be a few exceptional persons paying exceptionally high rates, a very rational state of affairs; and when the City of London had by the gradual extension of such experiments freed itself from its own smoke, I think we might safely rely upon the citizens to take care that the indirect economies to which they would be legitimately entitled by their public spirit were not destroyed by the unrestricted smoke production of the surrounding boroughs.

I have made the system of the general collection of smoke by mechanical means for the purpose of treatment the basis of my remarks, but I have already disclaimed any desire for exclusive privileges for that particular form of experiment in the purification of smoky air. If it be feasible on the commercial scale, it has the advantage in an especial manner of making successive improvements possible. The smoky air of London is injurious, not only on account of its visible soot, but also on account of the sulphurous acid and other invisible products of combustion which accompany the soot in the first instance. If it be found possible in the first place to deposit the soot particles, attention might next be turned to some means of dealing with the noxious acid fumes, at least, in those cases where they are specially abundant.

Such a system would thus be, in the first instance, a direct encouragement to progressive experiments, and in the end would enlist the active support of all those possessing arrangements for avoiding smoke in favour of effective compulsion for those who had not.

To put the questions I have indicated to men of science in this way would be merely a matter of business, and if the questions were so put, the science of the twentieth century would probably give as satisfactory an answer to the question of the treatment of smoke as the science of the nineteenth has given to the question of the treatment of sewage.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Hon. C. A. Parsons, M.A., F.R.S., whose scientific work in connection with the development of the steam turbine has excited much interest, has been elected to an honorary fellowship at St. John's College, of which he was formerly a scholar.

Mr. L. Doncaster, King's, has been appointed to work at the University table in the Naples Zoological Station.

A conference on the training of teachers for secondary schools for boys will take place in Cambridge, under the presidency of the Vice-chancellor, in November.

The Gedge prize for research in physiology has been awarded to Mr. S. W. Cole, King's.

ON Wednesday, October 22, Mr. Andrew Carnegie was formally installed to the rectorship of St. Andrew's University. In his rectorial address, Mr. Carnegie dealt with the economic changes in the relative position and power of nations which either have taken place or are impending. Among honorary degrees conferred on the occasion was one bestowed on Mr. Alexander Graham Bell, the inventor of the telephone.

WHILE agricultural education is in a flourishing condition in the colleges of the United States, it is not yet doing as much for the welfare of the American farmer as is desirable. This, at least, we infer from the vigorous address delivered by the Secretary of Agriculture before the National Educational Association, which is briefly referred to in an editorial article in vol. xiv. part i. of the "U.S. Experiment Station Record." Mr. Wilson pleads not so much for technical instruction in agriculture as for the *education* of "half the people under our flag, who till the soil and furnish 65 per cent. of our exports." The importance of this class warrants the special adaptation of the educational system to its needs. "The four-year college course does not begin soon enough nor continue long enough to meet the requirements of our day." Study should begin in the primary school and continue through life. Teachers and the organisers of education in rural districts should understand the farmer's requirements, should themselves know something of agricultural science, and to this end Mr. Wilson recommends that teachers in primary and secondary schools should be sent to agricultural colleges at State expense to get the necessary knowledge. While much might be done to awaken the interest of the rising generation in agriculture were the teachers in elementary schools possessed of an agricultural bias, it is doubtful if any such "entirely new" system as Mr. Wilson refers to in the following sentence would be practicable or desirable. "Five thousand students attend agricultural colleges, but these colleges are feeling their way in the dark along untravelled paths. . . They will at last forge out a system that will meet the requirements of producers and be entirely new and suitable to our conditions as a people."

IN the *North British Agriculturist* of October 22, a different and more direct method of awakening the interest of the young farmer in his work is described. Under the auspices of the

Berkeley Hunt Society, a competitive examination in agriculture, and especially in the arts of hedging, thatching, judging stock, &c., is held. The examination is open to young farmers and labourers of the district, is partly written, partly practical and oral. Three valuable prizes are offered and certificates are awarded for satisfactory work. The fall in prices and the scarcity of labour have made farmers less careful in details than formerly, and as a consequence their labourers are less skilled. Any kind of competition which revives the interest of masters and men in arts so necessary to good farming is much to be commended. If country districts held more competitions of this sort, if skill in rural arts were fostered with a tenth of the energy bestowed on foxes or football, we would hear less of rural depopulation and of agricultural depression.

THE last annual report of the Glasgow and West of Scotland Technical College shows that the high standard of the work accomplished in the institution is fully maintained. During the session 1901–2, the number of students in the various departments of the College reached 5651, of whom 596 were students studying in the day technological courses. Although the evening classes were attended by 4174 men and 220 women, the governors were unable to find room for some hundreds of students, who were perforce refused admission. In view of this serious want of accommodation, we are glad to learn that contracts, amounting to about 130,000*l.*, have been entered into for the erection of the first section of the proposed new buildings. The section will comprise about seventy-two per cent. of the whole structure, and fully three years will be occupied in its erection. It is anticipated that the new buildings, as planned, exclusive of equipment, will cost about 180,000*l.*, to which amount must be added 30,000*l.* for the site. The building fund, as shown by the list of donations given in an appendix to the report, now stands at 175,000*l.*, to which the Scottish Association of Master Bakers has contributed nearly 2500*l.*, the Glasgow Building Trades' Exchange about 650*l.* and the Trades' House and Incorporations of Glasgow an amount approaching 2000*l.* Nor is this the only evidence of the keen interest taken in higher education by Scottish manufacturers and merchants, for the report contains long lists of firms who have either given facilities for parties of students to visit works or have supplied the College with gifts of apparatus, specimens or laboratory material. That the claims of pure science have not been overshadowed by the pressing needs of the technological studies is shown by the gift of 5000*l.* from Mrs. John Elder for the provision of lectures on descriptive astronomy. There is evidently a great future in store for this deserving Glasgow institution.

SCIENTIFIC SERIAL.

Journal of Botany, October.—From the collection of plants made by Mr. T. Kassner chiefly along the railway from Mombasa, in British East Africa, Mr. Spencer Moore selects for description the more interesting species of the Compositæ and Acanthaceæ, and proposes seven new species.—Mr. W. E. Nicholson refers some miniature mosses gathered near Crowborough, Sussex, to *Ephemerum stellatum*, a species first recorded by Monsieur Philibert for specimens collected at Bruailles, in France.—A note on the genus Sematophyllum signifies Mrs. E. G. Britton's approval of the revival of that genus of mosses by Dr. Braithwaite.—Mr. G. C. Druce gives a brief account of the plant establishments on the shingle near Dungeness, and a list of Kentish plants which adds a few new localities to those recorded in Hanbury and Marshall's "Flora of Kent."—Mr. S. T. Dunn, by an inductive method of argument, deduces that only one species of the British representatives of the deadnettles, *Lamium Galeobdolon*, has maintained its original habitat and may be considered naturally indigenous.—A list of West Lancashire plants, by Messrs. J. A. Wheldon and A. Wilson, provides new county records and localities.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 1.—The Rev. Canon Fowler, president, in the chair.—Mr. H. St. J. Donisthorpe exhibited specimens of *Dibolia cynoglossi*, taken by him near Pevensey on August 11 last. He said that the beetle, which was figured by Curtis, had not been recorded as British since 1866.—Mr. O. E. Janson exhibited a fine hermaphrodite specimen of *Dryas paphia*, taken in the New Forest by Mr. Herbert Charles on July 28 and recorded in the *Entomologist*, also a melanic specimen of *Papilio demoleus* from Ceylon, in which all the usual marginal and submarginal yellow markings were absent and the discal markings much obscured; on the underside the yellow markings were entirely wanting.—Mr. C. P. Pickett exhibited a ♂ *Callimorpha dominula* with the hind-wings suffused with black and an extra black spot in the centre, the white spot on the fore-wings being absent, and a very large ♀ of the same species, both bred from larvæ found at Walmer at the end of March; also three aberrant specimens of *Triphaena fimbria* bred from larvæ taken at Wood Street during the same month.—Mr. C. O. Waterhouse exhibited specimens of a wasp, *Zethus chalybeus*, and a neuropteron, *Mantispa semihyalina*, received with a collection of Hymenoptera from Rio Janeiro, suggesting a curious case of mimicry.—Mr. F. B. Jennings exhibited specimens of *Hister merdarius*, from Broxbourne, Herts, part of a large colony of this usually scarce species found with *Hister 12-striatus* and other beetles inhabiting a heap of a chemical substance, probably gas-lime, in which also many larvæ, presumably of *Hister merdarius*, and burrows were observed. The soil was warm and moist, and this, and the presence of a quantity of vegetable refuse thrown on the heap, was no doubt the attraction to the Histers to settle there.—Mr. A. J. Chitty exhibited a specimen of *Metoecus paradoxus* with a part of the cells of a nest of *Vespa vulgaris*, in which place the beetle is invariably found. The beetle in the cell tucks in his head, only displaying on the surface the thorax, which is coloured similarly to the face of the wasp. This peculiarity suggests a case of mimicry, and Prof. Poulton said that it fitted in with the case of some other bees and wasps.—Mr. H. Rowland-Brown exhibited on behalf of Mr. G. F. Leigh, of Durban, a ♀ and ♂ specimen of a rare noctuid, *Musgravia Leighi*, Hampson, discovered by him in Natal, and read remarks upon the life-history of the species, communicated by the captor.—Mr. Stanley W. Kemp exhibited two additions to the British list of Coleoptera, *Bembidium argentiolum*, from Lough Neagh, Armagh, and *Laemostenus complanatus*, from the neighbourhood of Dublin, taken in June.—Mr. W. J. Kaye exhibited examples of *Heliconius Lindigii*, *Heliconius antiochus* and *Morpho achilles* from British Guiana with notches taken out of the hind-wings, presumably by birds, to illustrate that these distasteful or warning-coloured species are subject to attack, this helping to show that experimental tasting as propounded by the Müllerian theory of mimicry does exist and go on.—Prof. L. C. Miall, F.R.S., communicated a paper by Mr. T. H. Taylor entitled "The Tracheal System of Simulium."—Prof. Auguste Forel communicated a paper entitled "Descriptions of some Ants from the Rocky Mountains of Canada (Alberta and British Columbia) collected by Edward Whymper."—Dr. T. A. Chapman read a paper entitled "On *Heterogynis paradoxa*."

Royal Microscopical Society, October 15.—Dr. H. Woodward, F.R.S., in the chair.—Prof. T. G. Bonney, F.R.S., gave a demonstration on rock changes in nature's laboratory.

PARIS.

Academy of Sciences, October 20.—M. Bouquet de la Grye in the chair.—Studies on earth, by M. Th Schloesing. In a previous paper the author has shown that the distribution of the ferric oxide varies with the size of the earth particles. In the present paper a similar result is obtained for the organic matter. The earth was separated into particles of varying fineness by levigation and the amount of organic matter determined in each, the percentage varying from 0·15 in the coarsest particles to 7·8 in the finest. A hypothesis is developed to explain these results, which it is proposed to submit to experimental verification.—On the mode of action of carbonic acid in experimental parthenogenesis, by M. Yves Delage. It has been shown that the addition of carbonic acid communicates to sea water the property of developing parthenogenetically the eggs of Asterias. Its effect is now considered from the points of view of its acidity, anæsthetic action, asphyxiating power and effect on osmotic pressure, and the conclusion is drawn that parthenogenetic agents act as temporary poisons. Carbonic acid is a perfect agent because it completely poisons the eggs, but its action is absolutely temporary, and after its elimination the protoplasm is unchanged.—On some parasitic protozoa in *Damonia Reevesii*. by MM. A. Laveran and F. Mesnil.—On the problem of the brachistochrone, by M. Haton de la Goupillière.—Remarks by M. R. Zeiller on his note in *Palaeontologia Indica* entitled

"Observations on some Fossil Plants of the Lower Gondwanas."—Remarks by M. Dubail on a volcanic eruption at the island of Torishima, Japan.—On the formation of liquid drops and Tate's laws, by MM. Ph. A. Guye and F. Louis Perrot. The formation of drops of water, benzene and aniline issuing from a capillary tube has been studied photographically by means of the kinematograph. The photographs were taken under two conditions, one in which the drops were formed slowly (statical drops) and the other in which the rate of growth was increased (dynamical drops), and a plate is given showing a typical set of the forms observed in each case. The separation of the drop offers a great analogy with the rupture of metallic wires under traction; the rigidity of the liquid is consequently one of the elements of the problem. The authors conclude that the laws of Tate do not correspond to the facts observed, and hence should be abandoned.—On the elastic parameters of silk fibres, by M. F. Beaulard. In spite of the frequent use of silk fibres in bifilar suspensions, the elastic properties of this substance do not appear to have been determined. In the course of the experiments it was found that silk fibre is affected by hysteresis and undergoes permanent deformations.—Thin metallic films obtained by kathode projection, by M. L. Houllevigue. Mirrors of platinum, palladium, iron, nickel, cobalt, copper and bismuth have been prepared by this method, but no trace of deposit could be obtained from carbon. A bismuth film prepared in this way and placed normally in a strong magnetic field showed no variation in its electrical resistance; from this it would appear that bismuth obtained by kathode projection is absolutely amorphous. Transparent films of iron placed normally in an electromagnetic field showed the existence of a magnetic rotatory power without difficulty.—The action of mixed organomagnesium compounds on the esters of ketonic acids, by M. V. Grignard. The interaction of CH_3MgI with isoamyl pyruvate, ethyl phenylglyoxylate, ethyl levulate and ethyl acetosuccinate has been studied, and brief descriptions of the resulting products are given.—On the derivatives of ethyl pyruvylpyruvate, by M. L. J. Simon. A substance to which the constitution of ethyl pyruvylpyruvate has been assigned is produced by the consecutive action of aniline and strong sulphuric acid upon ethyl pyruvate. In order to demonstrate clearly the ketonic nature of this substance, its interaction with phenylhydrazine has been studied. Two isomeric hydrazones are produced, the preparation and properties of which are fully described.—The germination of the spores of *Sterigmatocystis nigra* in the trachea of some birds, by M. Pierre Lesage.—Experiments on the germination of pollen grains in the presence of stigmata, by M. Pierre Paul Richer. The pollen of a certain number of species, which do not germinate in pure water, germinate if stigmata of the same, or closely allied, species be added.

DIARY OF SOCIETIES.

FRIDAY, OCTOBER 31.

PHYSICAL SOCIETY, at 5 p.m.—On the existence of a Relationship between the Spectra of some Elements and the Squares of their Atomic Weights: Dr. W. Marshall Watts.—The Size of Atoms: H. V. Ridout.—Exhibition of "Vacuum Calorimeters." Prof. H. L. Callendar, F.R.S.

INSTITUTION OF MECHANICAL ENGINEERS, at 8 (Extra Meeting).—Discussion of the Paper on Oil Motor Cars of 1902: Captain C. C. Longridge.

MONDAY, NOVEMBER 3.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Preliminary Investigation of the Chemical Charges produced by various Reagents on Guttapercha: Sir William Ramsay, K.C.B., F.R.S.—Also, *time permitting*, The Reduction of Ammoniacal Silver Solutions by Organic Substances: Dr. G. T. Morgan.—A simple Qualitative Test for Bromides and Iodides: Dr. F. Mollwo Perkin.—The Influence of Impurities on the Specific Gravity of Sulphuric Acid: Arthur Marshall.

SOCIETY OF ENGINEERS (Royal United Service Institution), at 7.30.—Effect of Segregation on the Strength of Steel Rails: Thomas Andrews, F.R.S.

TUESDAY, NOVEMBER 4.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Address by the President, and presentation of Medals and Prizes awarded by the Council.

ZOOLOGICAL SOCIETY, at 8.30.—An Account of Recent Palæontological Discoveries in Egypt: Dr. C. W. Andrews.—On the Classification of the Fishes of the Suborder Plectognathi, with Notes and Descriptions of New Species from Specimens in the British Museum: C. Tate Regan.—On the Transformations of *Papilio dardanus* and *Philampelus megaera* and on two new Species of South-African Heterocera: Lieut.-Colonel J. Malcolm Fawcett.

WEDNESDAY, NOVEMBER 5.

COLD STORAGE AND ICE ASSOCIATION (Institution of Mechanical Engineers), at 8.—The Technical Application of Liquid Air: Dr. Carl Linde.

SOCIETY OF PUBLIC ANALYSTS, at 8.—(1) The Reactions of the Alkaloids of Ipecacuanha; (2) The Analysis of Preparations containing Opium: Alfred H. Allen.—The Estimation of Salicylic Acid: Sidney Harvey.—Volatility of Aqueous Solutions of Acetic Acid: William Chattaway.

GEOLOGICAL SOCIETY, at 8.—The Fossil Flora of the Cumberland Coal-field, and the Palæobotanical Evidence with regard to the Age of the Beds: E. A. Newell Arber.—Notes on Mr. E. A. Newell Arber's paper on the Clarke Collection of Fossil Plants from New South Wales: Dr. F. Kurtz.—On a New Boring at Gaythorpe (Lincolnshire): Henry Preston.

ENTOMOLOGICAL SOCIETY, at 8.—New Indian Hymenoptera: Major C. G. Nurse.—Notes on *Drilus flavescens*, Rossi: L. R. Crawshay.—New Species of Indian Chrysididæ: Major C. G. Nurse.

THURSDAY, NOVEMBER 6.

LINNEAN SOCIETY, at 8.—Notes on a Natural History Journey to Chile: H. J. Elwes, F.R.S.

RÖNTGEN SOCIETY, at 8.30.—Address by the President, Mr. Herbert Jackson.

CHEMICAL SOCIETY, at 8.—Di-Indigotine: J. Moir.—Note on the Localisation of Phosphates in the Sugar Cane: C. H. G. Sprankling.—The Specific Heats of Gases: H. Crompton.—On the Non-existence of the Gaseous Sulphide of Carbon described by Deninger: E. J. Russell and N. Smith.—The Action of Nitric Acid on Bromophenolic Compounds: W. Robertson.—Hydroxyoxamides. Part II.: R. H. Pickard, C. Allen, W. A. Bowdler and W. Carter.—3:5-Dichlor-*o*-xylene and 3:5-Dichlor-*o*-phthalic Acid: A. W. Crossley and H. R. Le Sueur.—Isometric Anhydrous Sulphates of the Form $M''SO_4,R'_2SO_4$: F. R. Mallet.—The Catalytic Racemisation of Amygdaline: J. W. Walker.—The Combination of Carbon Monoxide with Chlorine under the Influence of Light: G. Dyson and A. Harden.—The Constituents of Commercial Chrysarobin: H. A. D. Jowett and C. E. Potter.
